PURIFICATION.—Sulphur occurs in commerce in several states of purity, the native sulphur being the most impure. In order that it may be more fit for the several uses to which it is applied, it is partially purified from the grosser extraneous matter, such as gravel, sand, *et cetera*. This is done, according to some authors, by throwing a quantity of the crude native sulphur into a suitable iron vessel or pan, and heating this pan until fusion takes place. The sulphur when fused, of course, occupies much less space than it did in the heap, so the operator keeps filling up the pan until it is full of the fused sulphur. A high heat is not advantageous. This may be inferred from what has been said before respecting the changes which take place during the fusion of sulphur at different temperatures. For the purpose of purification the lowest heat consistent with perfect fusion is the one to be employed. The liquid sulphur is thus in its thinnest state, easily allowing the heavy particles with which it was contaminated to fall to the bottom of the pan, while any light particles rise to the top, and are skimmed off. When some time has elapsed, and the operator considers that sufficient subsidence has taken place, he proceeds to remove the upper stratum of tolerably pure sulphur, running it into moulds, from which it is removed as solid blocks of sulphur. That the method is not perfect is easily ascertained by burning a piece of ordinary commercial sulphur in a porcelain capsule. A quantity of light dust will remain,

consisting to a large extent of sulphate of lime; yet, though the purification is not absolute, it produces an article pure enough to be employed for almost every purpose required in the arts. In order to procure an almost absolutely pure article, such as is necessary for medical and a variety of other purposes, distillation, or rather sublimation, must be had recourse to. Sulphur, as has been before stated, is perfectly volatile; a ready method therefore exists of separating it from all bodies which are not so. It is said that the following apparatus—Fig. 567—is employed to effect this. A A, are two earthenware or fire-clay jars,

Fig. 567.

standing on a raised support of bricks. The mouths of these jars protrude slightly over the top of the furnace. This is for the purpose of readily enabling the operator to fill in the charge, and to remove the earthy residuum. A hollow tube or arm projects laterally and slightly downwards from each of the pots or retorts, which arm is thrust into another pot or vessel to receive the sublimed sulphur which condenses into it. When the subliming pot has received its charge, the lid is luted on and the furnace lighted. As they become heated, the various changes of fusion take place up to the last, when sublimation begins. The vapor then passes over into the condensing jar, and becomes solid. All the extraneous matter is left in the subliming pot, from whence it is removed prior to the introduction of another charge. This apparatus, *if actually employed*, could certainly furnish only a small quantity of sulphur. It is hardly possible to imagine a large gunpowder work using such an apparatus.

In 1815 a manufacturer named MICHEL, of Marseilles, devised an apparatus which, with some slight modification, is used up to the present day. The drawing—Fig. 568—represents it, and which, like the one previously described, contains a retort wherein the sulphur is converted into vapor, and a condensing chamber in which this is reconverted into solid sulphur. The apparatus, as in the drawing, consists, first, of a retort, C, beneath which is a furnace, A; this retort is filled with liquid sulphur from the reservoir, B, wherein the crude sulphur is melted by the waste heat of the furnace to facilitate its introduction to the retorts. When the retort has become sufficiently hot the sulphur begins to pass as vapor through the tube or opening, D, into the condensing chamber, E. This chamber is built entirely of brick, with a well-cemented brick floor; on its upper part a small chimney is erected; this chimney contains a sort of wooden valve or door, capable of opening outwards, to allow the expanded air to escape, and in case of explosion to allow the gases produced immediate exit. This apparatus when cold allows solid sulphur

to form at once in the shape of the ordinary commercial *flowers* of sulphur; the vapors immediately on coming into contact with the cold chambers are chilled, and fall as a minutely divided solid. These flowers, as they

Fig. 568.

are called, are removed before the chamber gets hot, which is the case after a few days' working, the whole of the heat which the sulphur had taken up, in order to become vapor, being given out to the walls; they thus acquire so high a temperature as to fuse sulphur, therefore it can no longer become solid in contact with them, but condenses on their surface in a liquid form, and runs to the bottom, where it collects. When the operator is satisfied that sufficient has distilled over, he proceeds to remove it; this he does by means of the plug apparatus, figured at F, which is simply an iron plug with a tolerably long shank or handle, as is shown in the drawing; by pushing this plug inwards he opens the passage for the flow of the liquid sulphur, which runs into suitable moulds, to form the *stick or roll* sulphur of commerce. The residue is raked out of the retort, which is immediately charged again by removing the plug which closes the tube or passage between the vessel, B, and the retort. An apparatus better calculated for the purpose than the above, is figured in PAYEN's *Precis de Chimie*, in which two retorts are attached to one condensing chamber; these retorts are cylindrical, and resemble to a certain extent ordinary gas retorts. A portion of the door which closes the outer end of the retort is movable, to enable the operator to rake out the debris left after distillation, the other end of the retort rises like a swan's neck before opening into the condensing chamber. Over these openings or orifices within the chamber hangs a damper or register in such a manner that it can, from the outside, be placed over them, thus cutting off all communication between the retort and the chamber.

A fusing vessel heated by the waste heat is attached, as in the drawing just given. This description of apparatus has the advantage, that by its means the operation can be rendered continuous. For instance, let one retort be called A, the other B; suppose retort, A, charged at a certain hour, and retort, B, charged some two hours later, it is certain that were they charged with an equal weight of raw material, the retort, A, would be ready for recharging two hours before retort, B. Supposing this to be the case, the damper or sliding plate is allowed to fall over the opening of retort, A, thus closing the passage between it and the condenser, and preventing the rushing back of any sulphur vapor. The cover is removed from the front opening, the impure residue raked out, after which it is again closed, the entrance into the condensing chamber is again opened, a charge of sulphur is run in from the fusing vessel, and the distillation again commences. During the whole of these operations retort, B, has been uninterruptedly at work; but eventually the same operations have to be performed in connection with it as have been detailed with respect to retort, A. Thus between the two a constant stream of sulphur vapor is being perpetually driven into the condensing chamber, the work going on almost without interruption, as the retorts never want charging simultaneously.

Sulphur thus produced is almost pure. It is true that the sublimed sulphur in powder—that is, the flowers of sulphur—contains a small quantity of sulphurous acid, which for some purposes it is necessary to remove by washing with water, but this is pretty nearly the only body it is contaminated with; the roll sulphur is free from sulphurous acid.

Sulphur occurs in commerce in another form intended expressly for medical use. When in this shape it is called *milk* of sulphur, and consists of sulphur in a very minute state of division. It is obtained in this state by dissolving ordinary roll sulphur bruised, or the flowers, in any caustic alkali, either soda, potassa, or lime; the latter used as being cheaper, and furnishing, as will be explained hereafter, a convenient adulterant. Sulphur does not dissolve in the alkaline solutions in the same manner that it does in turpentine, or any of the before-mentioned solvents. When boiled with an alkali a series of chemical compounds or salts are formed; in spiritous liquids it is a case of simple solution, exactly the same as dissolving sugar or salt in water, whereas in the other, a series of definite chemical phenomena takes place. If to a boiling solution of caustic potassa there is added as much sulphur as it will possibly take up, a liquid will be obtained containing sulphide of potassium, and hyposulphite of potassa, according to the following equation:—

In the first instance, while there is an excess of alkali, and little sulphur taken up, there is formed only sulphide of the alkaline metal and sulphite of the alkali; but this sulphite, by being boiled with an excess of sulphur, takes up another equivalent of it, being itself converted into hyposulphite. The clear liquid obtained in this way must be filtered or poured off the sediment, and excess of sulphur, and either sulphuric or hydrochloric

acid added until the liquid reddens litmus paper, when the dissolved sulphur is again precipitated in an exceedingly fine state of division. This is washed, drained, and dried at a gentle heat. It remains to examine the reaction by which the sulphur is again obtained. To do this, it will be well first to notice what the effect would be of adding acid to separate solutions of the two salts which form the mixture. If a solution of sulphide of potassium be taken, and an acid be added, a copious evolution of sulphide of hydrogen ensues, and there is obtained very little, if any, precipitated sulphur. Again, if acid is poured into a solution of hyposulphite of potassa, only a little sulphur will be separated. Hyposulphurous acid consists of sulphurous acid plus one equivalent of sulphur. Now hyposulphurous acid can only exist in combination; when set free it is instantly decomposed into sulphurous acid and sulphur— $\text{S}_2\text{O}_2 = \text{SO}_2 + \text{S}$. This is the case on adding an acid to hyposulphites. In the first place, the alkali is detached from its combination, and this hyposulphurous acid being set free gradually resolves itself into sulphurous acid and sulphur.

It is well known that when sulphide of hydrogen and sulphurous acid are brought into contact with each other a decomposition ensues, water and sulphur being the result, as shown in the following equation:—

Thus is explained the reproduction of the whole of the sulphur employed. Hyposulphurous acid and hydrosulphuric acid, or sulphide of hydrogen, are set free in the first instance; the hyposulphurous acid splits into sulphur and sulphurous acid, the latter immediately reacts upon the sulphide of hydrogen, producing together sulphur and water. This reaction is not very complete, although it is nearly so—the more correct reaction is given under *Pentathionic Acid*. In ROYLE'S *Materia Medica* it is recommended, in order to obtain milk of sulphur, to boil one part of sublimed sulphur with two parts of slaked lime and sufficient water, and to add hydrochloric acid to the clear liquid obtained.

Lime is almost invariably used by the manufacturers as a solvent, but they are guilty of substituting sulphuric acid for hydrochloric as a precipitant. By so doing, instead of forming the soluble chloride of calcium, which is easily removed by washing, they form the very insoluble sulphate of lime which, mixed with the sulphur, forms the article commonly sold by druggists as milk of sulphur, and thus what should be pure sulphur is contaminated by this worse than useless sulphate of lime, often to the extent of more than fifty per cent. In one sample obtained from a druggist, and which was stated to be pure, fifty-six per cent. of sulphate of lime was found. It is useless to argue that such a sophistication is harmless; for, although not positively poisonous, the introduction into the stomach and bowels of a quantity of this insoluble matter cannot but be productive of harm. Sulphur is used in medicine as a mild purgative, and in some skin diseases. The stores of sulphur which this country possesses, in one form or another, has not been overlooked by practical scientific men.

EXTRACTION OF SULPHUR FROM ITS ORES.—The immense quantities of sulphur stored up in the shape of sulphate of lime and baryta, as well as the sulphides of iron, zinc, lead, and copper, is almost beyond calculation. There is good reason to suppose that at some future time the sulphur combined with these metals, and which at the present time is separated from them only to be thrown into the air, will be recovered in a tangible solid form, at a price low enough to compete with foreign sulphur. The attempts to do this already have been numerous. In many parts of the country iron pyrites is plentiful, and this mineral appears to have been a favorite material with inventors. It is a mixture of bisulphide and protosulphide of iron. The second equivalent of sulphur of the bisulphide is held rather loosely, so much so that a red heat, continued for some time, will drive it off, leaving one equivalent of iron combined with one of sulphur, forming the protosulphide. Here, it would appear, a process for obtaining sulphur readily is at hand; but if it be considered that the sulphur ores of this country rarely contain more than thirty per cent. of sulphur, and that, at the most, but two-thirds of this exist as bisulphide, and that only half of this latter quantity can be expelled by heating with exclusion of the air, it will at once be apparent that the process could never be rendered remunerative. Such a method is, however, pursued in some parts of the Continent, where sulphur ores are found of a much richer kind, and in which there is also a greater proportion of bisulphide, but not exactly by the same method that sulphur is purified. The process appears to be one of slow distillation of one part of the sulphur, at the sacrifice, by combustion, of the other. It is stated—KNAPP—that not more than one-fourth of the sulphur actually contained in the pyrites is obtained. This process has formed the base for several improvements. It would appear that inventors are quite aware of the benefits that would result from the discovery of a process whereby sulphur could be separated from the pyrites on the spot, even if only the saving the expense of carriage, if nothing else, of the vast quantity of iron. The following process was invented by Mr. LEE. He first converts the sulphur in the pyrites, or other mineral, into sulphurous acid, and then proceeds to recover the sulphur from this by passing it through a quantity of coke heated to bright redness. The oxygen of the sulphurous acid combines with the incandescent carbon, forming carbonic oxide, *et cetera*, while the sulphur is left in a free state, and in vapor. It passes on to a suitable condenser, in which the bulk of it is recovered in a melted shape; that which escapes melting is received into a vaulted chamber similar to the one employed in the refining of sulphur by sublimation, and in these obtained solid in the form of flowers of sulphur.

This process, or rather the apparatus, appears to be of a very complicated character. Mr. SPENCE of Manchester, in a process patented by him a few years ago, has materially simplified it, although he works on precisely the same principle. Mr. SPENCE'S apparatus consists simply of an ordinary pyrites burner, such as is used in the manufacture of sulphuric

acid, to which is attached a number of condensing vaults. He charges his burner with alternate layers of charcoal and the pyrites under treatment; having first heated the brickwork of the burner up to the proper pitch. When at work, the action is very simple—the pyrites burns with production of sulphurous acid; each atom of this gas has to traverse a bed or layer of red-hot charcoal. Now, as just before stated, carbon having a greater affinity for oxygen than sulphur has, forces this sulphurous acid to yield up its oxygen, thus setting the sulphur free. The sulphur passes on with the current of gases, and is deposited in a state of powder in the condensing chambers. This plan appears to be more feasible, and better capable of working on a large scale than the one preceding.

While speaking of precipitated sulphur, it was shown how it was possible for sulphide of hydrogen and sulphurous acid gases to react upon each other, the eventual products being water and sulphur. This reaction has been taken advantage of in a process patented by Mr. DUCLOS of Swansea. He proposes to conduct into a leaden chamber, such as is used in the production of sulphuric acid, a mixture of two volumes of sulphide of hydrogen and one volume of sulphurous acid, a quantity of steam being at the same time admitted into the chamber. This, at first sight, appears to be very workable. It is easy to see that the two gases could be regulated to each other, and a constant action go on: the sulphur in a fine state of division would be deposited on the floor of the chamber, while the excess of atmospheric air, *et cetera*, would go out through proper openings at the end of it. But it unfortunately happens that only about one-half of the sulphur actually contained in the two gases is obtained. When these two gases are brought together, water being present, the results actually are water, sulphur, and pentathionic acid—an acid of sulphur with the formula S_5O_6 . Its production may be explained as follows—

that is to say, that five equivalents of sulphurous acid and five equivalents of sulphide of hydrogen produce, by their mutual reaction, five equivalents of water, five equivalents of sulphur, which are deposited, and one equivalent of pentathionic acid. By calculation it is thus found that by this only one-half of the sulphur would be obtained in the solid state, for in the sulphurous acid there are five equivalents of sulphur, and five more in the sulphide of hydrogen; and for these ten equivalents of sulphur one recovers only five, the rest going to form the pentathionic acid, a body for which no use in the arts has yet been found. Thus, instead of burning the pyrites, or other minerals, and endeavoring to separate the sulphur from the sulphurous acid produced, it would be more economical to convert it into sulphuric acid at once.

Mr. GOSSAGE surmounted the pentathionic acid difficulty, by causing the reaction to take place at a high temperature. His process is peculiarly applicable to the reproduction of the sulphur contained in the lime compound or alkali waste thrown away by the soda manufacturers. As is well known, the whole of the sulphur used in the manufacture of the alkali finds

its way into the vat waste. Mr. GOSSAGE proceeds to decompose this vat waste by means of carbonic acid. The action of this acid causes sulphide of hydrogen to be evolved. A portion of this sulphide of hydrogen is converted by burning into sulphurous acid, which sulphurous acid is made to react, at a high temperature, on a fresh portion of sulphide of hydrogen, when water and sulphur are produced. His apparatus consists of four distinct portions—the first for the production of the requisite carbonic acid; the second for the decomposition of the alkali waste; the third is for the decomposition of the sulphide of hydrogen; and the fourth for the collection of the sulphur produced. The apparatus for the production of the carbonic acid is an ordinary lime-kiln, with some additions to render it more fit for the special purpose to which it is to be applied. It is fed with a mixture of common coke and limestone, air being admitted for the purpose of combustion in the usual manner. The apparatus is of the continuous kind. It is fed constantly at short intervals with the above materials, the quicklime produced being removed from the bottom of the kiln at stated periods. The action of this kiln is simply the decomposition of the limestone, the carbonic acid evolved, together with that furnished by the combustion of the coke, being carried to where it is needed in the next stage for the decomposition of the vat waste.

The composition of this compound may be considered definitely settled. It seems to be tacitly allowed with DUMAS that its composition is $2 \text{CaS} + \text{CaO}$, or two equivalents of sulphide of calcium, united to one of lime; but the research of Mr. J. W. KYNASTON lately in the Editor's laboratory, has indubitably proved it to be simply a protosulphide of calcium with carbonate of lime. This substance, the composition and properties of which have been fully discussed under the article SODIUM, though insoluble in water, is capable of being decomposed by carbonic acid, especially when in a loose porous state; one equivalent of the lime compound, and three equivalents of carbonic acid producing three equivalents of carbonate of lime, and two of sulphide of hydrogen, as follows:—

The apparatus employed, or proposed to be employed, in the decomposition of this compound by Mr. GOSSAGE, consists of two large chambers, or rather large columns, filled with numerous perforated floorings or stages on which the alkali waste is placed; these chambers or columns are placed side by side, and so connected together, that the carbonic acid which is admitted at the bottom of one column, emerges at the top, and is conducted by a proper passage to the bottom of the adjoining column, up which it passes, as in the previous case. The material to be operated upon is laid on the perforated floors, in a loose open manner, to facilitate the passage of the carbonic acid; this ascending from the bottom of the column, penetrates through each of these separate masses, decomposing each particle with which it comes in contact. This course it pursues until it reaches the terminal point of this portion of the apparatus, at which time the carbonic acid is supposed to have been completely absorbed, and replaced by the

liberated sulphide of hydrogen which has now to be decomposed. In order to this effect, the inventor has constructed a furnace of a rather peculiar character. This furnace has a closed ash-pit, or an ash-pit whose inlet can be closed or not, at pleasure, by means of a damper or register; the flue or passage for the gases leading from the waste decomposer is divided into two at this point, one part of the sulphide of hydrogen is drawn into this ash-pit, and so through the bars and fuel of the furnace, while the other portion is admitted immediately above the burning fuel; by this means a quantity of sulphurous acid is produced, which, in coming in contact with a fresh portion of sulphide of hydrogen at this high temperature, decomposes it, forming, as shown before, sulphur and water. This sulphur, of course, is in the state of vapor, mixed or diluted with a variety of other gases; it now remains to separate this valuable ingredient from the mass of inert and useless gases which accompany it. For this purpose an apparatus similar to the one last described is employed. This column is built of bricks or other suitable material, and is filled with coke; a cistern of water is placed on the top, by means of which, with the assistance of an apparatus for the spreading of the water in the form of rain over the whole area of the column, the coke is kept drenched with a stream of water. The vapors issuing from the furnace, consisting, as before stated, of sulphur vapor, mixed with other gases, is forced or drawn in at the bottom of this column, when, meeting with the cold wet coke, their temperature is almost instantly brought below the melting-point of sulphur, and this body is deposited in the solid state in the form of an impalpably fine powder, which mixes with the stream of water, and is finally carried out with the stream, forming with it a milky liquid, which falls into a proper cistern or reservoir, from which the sulphur is separated by deposition; from thence it is removed, and fused into a coherent mass, to fit it for the purposes of commerce. Between each of the different portions of the apparatus just described, the inventor places an ordinary draught or blower-fan, which rapidly removes the gaseous products from one portion, forcing them into the next. The various columns, *et cetera*, are of such dimensions as to insure a sufficiently quick passage for the products.

In theory this would appear to be perfection, inasmuch as we have here the recovery of the sulphur, which is the main object; and also the recovery of the lime, this body being left as carbonate after decomposition. As most alkali manufacturers are also manufacturers of bleaching powder, or chloroxide of calcium, this process offers an unfailing supply of lime; or if the recovered carbonate of lime just spoken of should not be found to answer for the soda decomposition a second time, that produced in the kiln could be used in the black-ash furnaces, instead of the limestone usually employed. It thus offers a considerable advantage if it should turn out to be as practically valuable as it is theoretically interesting.

Messrs. M'DOUGALL and RAWSON, in a patent, dated May 21, 1849, claim a process for the reproduction of sulphur from sulphide of hydrogen, from whatever source obtained. This they effect by passing it through

a pipe, heated to a red-heat, wherein the gas is split up into its constituent elements, sulphur and hydrogen; the sulphur is collected in any convenient manner. This process does not appear eminently practical, if the experiments of CORENWINDER be correct. He states that by passing sulphur vapor and hydrogen over or through porous bodies, kept at a red-heat, he obtained sulphide of hydrogen, exactly the reverse of this process. At any rate in a laboratory M'DOUGALL'S operation answers perfectly.

Messrs. DYAR and CHISHOLME secured a patent in 1839, for the recovery or reproduction of sulphur from sulphurous acid. It consisted in submitting the gas while at a red-heat to the action of hydrogen, which latter seized upon the oxygen, forming water and liberating sulphur. Two furnaces of proper construction were erected, side by side, one adapted to the combustion of pyrites, the other constructed in such a manner that it afforded a stream of hydrogen, mixed with carbonic oxide, obtained by passing a current of steam through or among incandescent coke. The gases were brought together at a point of junction kept sufficiently hot by the combustion of the materials themselves. At this point the decomposition took place, the sulphur vapor passing on to a proper condensing apparatus.

Amongst a most numerous array of methods for procuring sulphur, or for separating it from natural combinations, perhaps one of the most theoretically ingenious is that mentioned by PARNELL as being devised by M. THAULOW. It is for producing sulphur from the natural sulphate of lime. He proposes to reduce this to the state of sulphide of calcium, which salt he then decomposes by means of carbonic acid, obtaining by this means sulphide of hydrogen and carbonate of lime. He effects the deoxidization of the sulphate of lime, or its reduction to sulphide of calcium by mixing it, in fine powder, with coal-dust, exposing this mixture to a red heat for a sufficient length of time in a retort of clay or iron; the carbon unites with the oxygen of the sulphuric acid and lime, and becomes carbonic acid, which he reserves, or immediately uses for the decomposition of a previous charge. Carbonic acid, as stated while describing Mr. GOSSAGE'S process, is able to decompose sulphide of calcium, driving off sulphide of hydrogen. Thus M. THAULOW proposes to burn sulphide of hydrogen in lieu of sulphur for the production of sulphuric acid. There are reasons for supposing that this process can never be successfully carried out. In the first place, as PARNELL observes, if the exact quantity of carbon only necessary to combine with all the oxygen present, is added, the reduction would be extended over a great length of time, and would probably never be complete; and again, were an excess of carbon to be employed, so as to hasten the decomposition, carbonic acid would not be obtained, for carbonic acid passed over red-hot carbon would part with half its oxygen, becoming carbonic oxide—CO—a gas which could not possibly be substituted for the carbonic acid in this case. By a little addition the process can be made theoretically possible; still, the probabilities are that it will never be practically worked, unless sulphur should rise in price much higher than it is likely to do.

As an instance of the manner in which old and useless, or exploded inventions again arise, one may mention the re-invention or revival of this very process by OTTO KÖHSELL, who patented it for the kingdom of Hanover in 1856. The process, as detailed by this inventor, is precisely the same in every detail as that of M. THAULOW—not the main principal only, but in every minute particular it is a perfect copy.

In 1857 Mr. GOSSAGE invented, and secured by patent—dated September 12th in that year—another process for obtaining the sulphur from the sulphide of calcium of alkali waste. In the place of hydrochloric or carbonic acid, as in his method of decomposition before mentioned, he liberates the sulphur in the form of sulphide of hydrogen, by acting upon the waste with steam at a high temperature. The following equation represents the change that ensues—

The sulphide of hydrogen so obtained he applies instead of sulphur, in the production of sulphuric acid by burning with atmospheric air, so as to form sulphurous acid gas; or he obtains the sulphur itself from the sulphide of hydrogen by causing sulphurous acid to act upon it, when mutual decomposition takes place.

When carbonic oxide gas is passed over the sulphates of the alkalis or alkaline earths in a state of ignition, the salts are reduced to sulphides with the simultaneous conversion of the carbonic oxide to carbonic acid, thus—

Now, as Mr. GOSSAGE has shown, if steam at a high temperature be caused to act upon the sulphides of the alkaline earths, sulphide of hydrogen is liberated. If, therefore, a mixture of steam and carbonic oxide gas be passed over the ignited alkaline, or earthy sulphates, the sulphur of the sulphate will be obtained as sulphide of hydrogen, and may afterwards be obtained in the free state. This method has been lately proposed by M. JACQUEMIN, for the production of sulphur from sulphate of lime, and also for obtaining, at the same time, soda in the caustic condition from sulphate of soda.

The author appears to think that by means of this process he will revolutionize the soda manufacture, as he anticipates the recovery of the whole of the sulphur in an available form without the production of any waste whatever. Even if this process would answer on a small scale, its success on a larger one is very doubtful. Were its success an absolute and undoubted fact, and the reaction clean and exact, it would be capable of considerable extension. The sulphur from sulphate of lime might be recovered in like manner. It would only be necessary to mix it in the manner M. THAULOW proposes to do with small coal, or other carbonaceous or reducing matter; heat to bright redness in a closed retort for some hours, until it was reduced to the state of sulphide of calcium; then to pass steam over and drive off the sulphur as sulphide of hydrogen, while lime would remain behind as

quicklime. This process, which is tacitly indicated by the author, should be much superior to that of M. THAULOW just mentioned; but it would appear that a like fate has awaited both processes; in fact, that they are each impracticable on a large scale, or, what is the same thing, they would not pay at present.

These are not the only methods which have been proposed for the recovery of sulphur from its various combinations; but they serve to show, to a certain extent, the industry of the various inventors who have turned their attention to the subject; and though success has not followed to the extent no doubt expected by the sanguine chemist, there is no reason for despair. It is still to be hoped that some one, more successful than his predecessors, may yet, in some fortunate moment, hit, either upon a yet latent reaction, or by some perhaps trifling variation of an already known mode of procedure, bring forward a simple and easily-worked process, that shall be all that could be desired, producing sulphur at a price sufficiently low to compete successfully with the imported article. Sulphur, in a state of combination, exists in this country in almost inexhaustible quantity. To separate this, and to produce it in a state of comparative purity, is what is wanted. When this is done, English manufacturers will be in a state of great independence. It scarcely need be added that by such a discovery the fortunate individual would be more than repaid for a life's industry.

COMBINATIONS OF SULPHUR.—Sulphur enters into many combinations, both simple and complex; it combines, with a few exceptions, with all the metals, forming with them proper insoluble compounds. The sulphides of the alkaline and earthy metals are soluble in water. Some sulphides are decomposed by acids, while others again are insoluble in these liquids. Of these peculiarities chemists avail themselves largely in analysis; for, by this property of forming insoluble compounds with sulphur, they are enabled to separate into classes several groups of metals, from which again, by a series of subdividings and subclassings, they can separate individually each element. The larger groupings are made chiefly through the instrumentality of sulphide of hydrogen. This gas, when passed through a solution of metallic oxides, in many cases throws down the metal as a sulphide, the gas being decomposed. As an example: if a current of sulphide of hydrogen be passed through a solution of a salt of lead, the following reaction takes place—

Sulphide of lead and water are the products of this decomposition. The following metals are thrown down as sulphides by sulphide of hydrogen from an acid solution—gold, platinum, mercury, silver, lead, bismuth, and copper, black; antimony, orange; arsenic, tin, and cadmium, yellow. The following metals are converted into sulphides when sulphide of hydrogen is passed through their alkaline solutions, or a slightly alkaline solution, in which their hydrated oxides are suspended—nickel, iron, and cobalt, yellow; tin, black; manganese, flesh-colored; zinc, white. Sulphur enters into the vegetal kingdom; it is found in more or less

quantity in many plants, chiefly in connection with nitrogen, with which it would appear to act in consort, at least in the organic world. In the animal kingdom it occurs pretty extensively also, and there too it is principally found in nitrogen compounds. Animal and vegetal products of the albumen and fibrin class contain it as an essential element, while its existence in the form of salt, as sulphate, *et cetera*, is still more diffused. It combines, as will be presently shown, with several proportions of oxygen, and with hydrogen in at least two proportions—the sulphide of hydrogen spoken of so repeatedly in this article when treating of the recovery of sulphur, and another body containing much more sulphur, its formula being given as HS_2 . This body is produced, appearing in the form of oily drops, which subside when a solution of pentasulphide of potassium is poured into dilute hydrochloric acid; it is very unstable; the greatest care and precaution cannot preserve it longer than a few weeks, even though it be sealed hermetically in a glass tube; it simply forms a link of the chain of combinations which sulphur is capable of forming.

The simpler combination with hydrogen is a well known body; it is the result of many decompositions, natural and otherwise; it is permanently gaseous, possessing a most nauseous odor, easily recognized as being the characteristic of several mineral springs, such as those of Harrowgate, *et cetera*. It is a product of the decomposition of many organic bodies, is evolved by putrid bodies, and is the cause of the smell of rotten eggs, the albumen of which, as before stated, contains a quantity of sulphur, is undergoing decay, and gives off its sulphur, or a part of it, as sulphide of hydrogen. This gas is prepared by adding an acid to any soluble sulphide, such as those of the alkalies, or of the alkaline earths. The most convenient, and consequently the most general method, consists in adding dilute sulphuric acid to sulphide of iron, placed in a bottle, closed with a cork, perforated with two holes, one for the passage of a tube funnel, through which sulphuric acid can be poured; while through the other is passed a tube for the exit of the gas—Fig. 569. If a slow

Fig. 569.

and constant stream of the gas is required, large lumps of the sulphide should be employed; but if, on the contrary, a rapid stream is needed, smaller lumps should be used. When the sulphide is introduced, the cork should be put in its place, and the requisite

quantity of dilute acid poured down the funnel; if the sulphide be good, a stream of gas bubbles will immediately begin to rise, and passing through the exit tube, can be directed through any solution, or to any required point. The decomposition which produces this gas from these materials is very simple—

that is, one equivalent of sulphide of iron, one of sulphuric acid, and one of water, produce one equivalent of sulphide hydrogen, and one of protosulphate of iron.

The combination of sulphur with nitrogen alone is of scarcely any importance, and need not be dwelt upon.

Sulphur and Carbon.—Sulphur forms several combinations with carbon; the one most marked and of the greatest importance, inasmuch as it is used in the arts, is the bisulphide of carbon or sulphocarbonic acid— CS_2 . It is formed by passing the vapor of sulphur over or through red-hot charcoal. This is effected by filling an iron or porcelain tube placed across a furnace—Fig. 570—with fragments of charcoal. One end of this tube is connected with a condensing apparatus—LIEBIG's tube will do—plentifully supplied with cold water. The other end of this tube must be capable of being closed tightly with a cork. When the tube is sufficiently hot the cork is removed, and small

Fig. 570.

pieces of sulphur are pushed through near to the charcoal. The orifice being again closed, the sulphur is converted into vapor, and in passing through the *interstices* of the *incandescent* carbon, combines with a portion, forming the body in question, which, passing on to the condensing apparatus, collects as a liquid. After sufficient time has elapsed a fresh portion of sulphur must be introduced, the operation being continued in this manner until sufficient has been prepared. This product is by no means pure, containing more or less sulphur which has escaped combination, and from which it must be freed by distillation in a glass retort placed in a water bath.

Bisulphide of carbon has a density of 1.272. It is, as obtained above, a transparent, colorless liquid, of a strong disagreeable odor. This odor is due to a foreign

body, the true smell being of a vinous or ethereal character. A considerable portion of this smell may be removed by shaking it up in a bottle with a quantity of strong sulphuric acid and bichromate of potassa. Bisulphide of carbon is a very volatile body, its boiling point being 110° . It rapidly evaporates, almost equaling sulphuric ether in this respect, diffusing its odor through the apartment. It is a very effective solvent fatty matter. Grease stains may be removed by it from paper or woven fabrics. It is only necessary to place a piece of blotting paper below the stain, and drop the bisulphide of carbon on it; it dissolves the grease, and the blotting paper receives the solution. When brushed the fabric must be exposed to the air, when the odor rapidly and perfectly disappears. Bisulphide of carbon is also a solvent of phosphorus; when a little bisulphide of carbon is warmed in a test tube and a piece of phosphorus dropped in it, it rapidly dissolves. This is a case of true solution. The phosphorus is again deposited unaltered on the evaporation of the solvent. It has been proposed to employ this solution in warfare. Shells filled with the solution were to be thrown into or on any combustible part of the enemy's premises, such as a wooden building or a ship's sails. The solvent evaporates, leaving a thin layer of phosphorus, or, in the case of a ship's sails, leaving every thread or fibre covered with a coating of phosphorus. This quickly begins to oxidize, and finally takes fire, which fire will communicate to the surrounding parts. The experiment may be performed on a small scale by wrapping a little tow round the end of a wire, and dipping this into the phosphoric solution, when, on taking it out and waving it about, the bisulphide of carbon almost instantly evaporates, and in a few seconds the tow takes fire, the phosphorus having ignited first.

Sulphur and Chlorine.—Sulphur also combines in a variety of proportions with other bodies, as well as those named. It forms combinations with phosphorus, boron, iodine, bromine, fluorine, and chlorine. One of its combinations with the latter body is used in the manufacture of caoutchouc; it is prepared by passing chlorine gas through melted sulphur, forming the dichloride of sulphur, which is found to contain also sulphur in solution. From this it must be freed by distillation, at a low temperature, and, if necessary, the rectification repeated until its boiling point is stationary at 228.2° . This chloride of sulphur has some curious properties; by means of it, a species of artificial india-rubber may be produced. To procure this body take a quantity of vegetal oil, say linseed or rape, and mix it with one-tenth its bulk of chloride of sulphur, and slightly warm the mixture; a strong reaction takes place. Hydrochloric acid is disengaged, and a mass remains, which, when washed with water, becomes white, and is as elastic as genuine caoutchouc, with precisely the same appearance. This curious body resists the action of boiling alkalies; ammonia and concentrated acids are without action on it, and it resists the solvent powers of alcohol, ether, sulphide of carbon, and oils.

Compounds of Sulphur and Oxygen.—Sulphur appears to have a great affinity for oxygen, with which it combines in many proportions, forming a series of

compounds, all of which are acids. The following are known to exist at present :—

Hyposulphurous acid,.....	$S_2 O_2$
Pentathionic acid,.....	$S_5 O_5$
Tetrathionic acid,.....	$S_4 O_5$
Triithionic acid,.....	$S_3 O_5$
Sulphurous acid,.....	$S O_2$
Hyposulphuric acid,.....	$S_2 O_5$
Sulphuric acid,.....	$S O_3$

Of this series two members have been already noticed—hyposulphurous acid and pentathionic acid. Hyposulphurous acid cannot be obtained in the free state, as already mentioned. When set free it splits up gradually into sulphur and sulphurous acid. It is commonly met with in the form of hyposulphite of soda, a compound employed to a considerable extent by photographers, it being a solvent of certain silver salts, which are insoluble in water, such as the chloride, iodide, and bromide. Hyposulphite of soda will also dissolve sulphate of lead, and in analysis affords a ready means of separating this salt from sulphate of baryta.

Hyposulphurous acid is comparatively stable when combined with a base. The hyposulphites of the alkalis and of the alkaline earths are those most frequently occurring. They are prepared in a variety of ways, the most common methods being either by exposing an alkaline or earthy sulphide to the air, when it absorbs oxygen, forming a quantity of hyposulphites and other salts; or by boiling a sulphite of the base with sulphur. The reaction in the latter case is very simple. Take the sulphite of soda for instance. This has the formula NaO, SO_2 . Add to this one equivalent of sulphur— $NaO, SO_2 + S$; and hyposulphite of soda— $NaO, S_2 O_2$ —is produced.

The following method appears to be a favorite one for preparing the hyposulphite of soda in small quantities :—One pound of pure crystallized carbonate of soda, is dried as perfectly as possible. When powdered, this is mixed with five ounces of pure sulphur, the mixture heated in a glass or porcelain basin to the melting point of sulphur, and kept at that temperature for some time, stirring constantly in order to bring every part into contact with the air. The sulphide of sodium formed at first absorbs oxygen from the air, and is converted with feeble incandescence into hyposulphite of soda. The mass, when cold, is dissolved in water, and boiled with sulphur for some time, and the liquid evaporated to the crystallizing point. Very fine and pure crystals are obtained in this manner. If the heat be too strong, part of the sulphur is burned off, and carbonate of soda remains undecomposed. In this case a second crystallization is requisite. Hyposulphite of soda can easily be obtained by passing a current of sulphurous acid through a solution of sulphide of sodium, boiling, filtering, and evaporating to the crystallizing point.

The earthy hyposulphites, as above stated, are formed by exposing their sulphides to the air; for instance, in a solution of sulphide of calcium exposed for some time in this manner, a considerable quantity of hyposulphites form by double decomposition. The hyposulphite of soda or potassa may be formed by adding to a solution of the sulphide of calcium a solution of the carbonate of these alkalies.

Hypsulphite of soda is used to a small extent in

analysis as a reducing agent, also as a means of separating iron and alumina, dependent on the fact that hyposulphite of alumina is not stable at much above the ordinary temperature. For instance, suppose iron and alumina are both contained in a solution; to this solution is added as much hyposulphite of soda as will convert these bases into hyposulphites; this is done while cold. The solution is now heated to boiling. Hyposulphite of alumina decomposes at this temperature into sulphur, sulphurous acid, and alumina, while the iron salt being more stable remains intact. The whole is now thrown on to a filter; when the iron salt passes through, while the alumina remains on the filter; and it is washed, dried, and ignited. The iron is separated from the filtrate in the usual manner.

This reaction is used, also, to a very small extent in calico-printing. A hyposulphite of alumina is formed in the cold by adding a solution of chloride of aluminium to a solution of hyposulphite of soda. The result is a solution of chloride of sodium and hyposulphite of alumina. This is thickened in the regular manner, and printed on the fabric. The piece is then exposed to a temperature of 212° by means of steam, when the salt is decomposed, alumina being deposited on or in the cloth. This alumina so deposited dyes up with madder precisely like the alumina precipitated in the ordinary manner from the acetate.

This method does not offer any advantage over that usually followed, except in certain cases, where it is a convenient course, on account of the ordinary method being inadmissible.

The rest of these sulphur and oxygen compounds, with the exception of sulphurous and sulphuric acid, are at present useless in the arts, but are valuable in a scientific point of view.

Sulphurous acid is composed of one equivalent of sulphur and two equivalents of oxygen. It is the irritating vapor or gas given off by burning sulphur. It may be prepared in a variety of ways, according to the purpose for which it is required. Two general principles may be followed, either the addition of a sufficient quantity of oxygen to sulphur, or the abstraction of oxygen from sulphuric acid.

When sulphur, as just stated, is made to burn in oxygen gas or common air, sulphurous acid is obtained. If it is desired to pass a stream of this gas through any liquid intended to absorb it, the sulphur must be burned in a close vessel or apparatus, which has a strong aspirator attached. The Woulf's bottle, or other vessel, must be placed between the vessel containing the sulphur and the aspirator, or, supposing this to be inconvenient, the sulphur may be mixed with some body containing oxygen loosely combined, and this mixture heated. A body possessing these requisite qualifications is found in peroxide of manganese. To obtain a stream

Fig. 571.

of sulphurous acid, it is recommended to make an intimate mixture of one part powdered sulphur, and seven or eight parts of black oxide of manganese. This mixture is placed in an iron retort, which is set on the fire. There is given off sulphurous acid, oxygen, and sulphur vapor, the matter in the retort being probably sulphide and sesquioxide of manganese. This method, not giving a very pure product, is not well adapted for many purposes. The method generally adopted is that of robbing sulphuric acid of one equivalent of oxygen by any convenient body. A mixture of strong oil of vitriol and charcoal heated in a flask, which has a conducting tube—Fig. 571—attached, serves very well, if absolutely pure gas be not needed. The gas given off by the mixture is a compound of SO_2 and CO_2 . The following being the reaction—

But sulphurous acid as nearly pure as possible, in fact quite pure, if made to traverse a little water to take up any sulphuric acid, may be obtained by heating sulphuric acid with one-third its weight of copper, in the shape of turnings or clippings. One atom of copper takes up one atom of oxygen from one atom of sulphuric acid, and becomes oxide of copper, which itself immediately combines with another equivalent of sulphuric acid, forming sulphate of copper—

Mercury may be substituted, but with no advantage—a like reaction takes place. The sulphurous acid so obtained is permanently gaseous at the ordinary atmospheric pressure, but is capable of assuming the liquid form, like carbonic acid, sulphide of hydrogen, and sundry other gases, at an increased pressure with a very low temperature. FARADAY employs a pressure of from three to five atmospheres; WACH places in a long glass tube, sealed at both ends and bent in the middle, a mixture of anhydrous sulphuric acid and sulphur. This is heated, while the opposite end is kept immersed in a freezing mixture. Sulphurous acid is formed under strong pressure, and condensed in the cooled end of the tube. In order to obtain it pure, it must be run to the other end of the tube, and again distilled to free it from sulphuric acid. Sulphurous acid in the liquid state is only of scientific interest; it is like many other rare chemical preparations, which are only made at a cost of great labor, and when made, can only be preserved conveniently for a very short time. As a liquid its boiling temperature is 14° .

As far as all the useful properties of sulphurous acid are concerned, they may be studied from its solution in water, this liquid taking up, at mean temperature, thirty-three times its bulk of the gas.

Sulphurous acid solution is obtained by passing a stream of the gas through cold water, employing for the generation any of the methods just given. A series of WOULD'S bottles, or other convenient apparatus, may be employed for the condensation. The contents of the first bottle should always be rejected, as it will contain a considerable quantity of sulphuric acid, carried over both mechanically and in a state of vapor; the other will be a nearly pure solution of sulphurous acid.

Sulphurous acid is capable of forming a crystalline hydrate with water. It is procured by exposing sulphurous acid vapor with water, in a tube or other apparatus, to a low temperature, by placing this tube in a freezing mixture. Solid sulphurous acid may be procured by rapidly evaporating the liquid acid—it forms white flakes. It is heavier than the liquid, and freezes at *minus* 110° . It is composed of—

Sulphur vapor, ... 1 } forming 6 vol. of spec. grav. 2.2113.
Oxygen gas, ... 6 }

Sulphurous acid is a powerful deoxidizer, instantly decoloring acid solutions of the manganates and chromates—in the latter case reducing them to the state of green sesquioxide of chromium. For analyzing the commercial sulphites, it is only necessary to weigh out a stated quantity of the sulphite or hyposulphite to be examined, dissolve it in water, make it acid with hydrochloric acid, and then to note the number of measures of a normal solution of bichromate of potassa required to be added to convert the sulphurous into sulphuric acid, and data are obtained from which the amount of sulphurous acid contained in the sample may be easily calculated. This reducing property of sulphurous acid has been turned to advantage by BUNSEN, in the indirect analysis of various bodies—for instance, in the valuation of manganese. He places the manganese in a flask, treats it with hydrochloric acid, passes the evolved chlorine into a solution of iodide of potassium; each atom of chlorine sets free an atom of iodine. When the operation is over, he disconnects the vessel containing this iodine, and adds from a burette a normal solution of sulphurous acid until the precipitated iodine has disappeared. Each equivalent of iodine converts an equivalent of sulphurous into sulphuric acid, as follows—

Thus, tracing the reaction back, one equivalent of sulphurous acid represents one equivalent of binoxide of manganese—this principle is applied in a variety of ways. The deoxidizing power of sulphurous acid is taken advantage of by the chemist in the estimation of arsenic. When arsenic exists as arsenic acid, it is very slowly thrown down by sulphide of hydrogen; whereas arsenious acid is easily precipitated. Sulphurous acid possesses the power of abstracting part of the oxygen from arsenic acid, reducing it to arsenious; so that, if a stream of sulphurous acid be passed through the arseniate to be analyzed, after making it acid with hydrochloric acid, it is converted into arsenious acid, which facilitates its precipitation when one comes to employ sulphide of hydrogen.

Sulphurous acid, passed through a dilute solution of yellow sesquichloride of iron, quickly reduces it to a protosalt—

Sulphurous acid reduces salts of gold, throwing down the gold in the metallic state. It is capable of taking up the second equivalent of oxygen from almost every metallic binoxide.

Sulphurous acid, in the shape of sulphite of soda, has been an article of commerce for some time, under

the half-fanciful and half-true appellation of antichlor. It has derived its name from the use to which it is applied, being used to correct the evil effects of an overdose of chlorine. In the bleaching of paper pulp, if any excess of chlorine or hypochlorite has been used, the sulphite, on being added, neutralizes it. If, for the sake of illustration, we imagine chlorine to have been used, then—

This hydrochloric acid can be taken up by any alkali, or will itself decompose a fresh portion of the sulphite, driving off sulphurous acid.

Sulphites are used by some in the manufacture of beet sugar. PROUST recommended them and a sulphurous acid solution as being antiferments, and having also other advantages. The following method of procuring it in large quantities was proposed by CALVERT, in a lecture lately delivered before the Society of Arts. He constructs a sulphur oven, such as is used in the manufacture of sulphuric acid. Within this oven the sulphur is burned, producing sulphurous acid. An earthenware tube, immersed in water, leads from this burner or oven to a tall wooden column filled with pumice-stone, or other suitable porous body. A cistern of water is placed on the top of this column, to which cistern a tap or valve is attached, by means of which a shower of water can be sprinkled on the pumice-stone, keeping it in a moist or wet state. The mixture of gases issuing from the burner, consisting of sulphurous acid, atmospheric air, and residual nitrogen, pass along the conducting tube, enter the column near the bottom, and pass up its whole length, thus meeting with the descending water; the sulphurous acid is absorbed, and a constant stream of the solution issues into a cistern placed at the bottom for its reception, while the residual gases pass out into the atmosphere.

Some brewers employ a solution of sulphurous acid to rinse out beer barrels after washing, as it possesses the property of arresting the acetic fermentation.

Sulphurous acid, when present in a free state in small amounts, is easily detected by its suffocating odor. It does not, like sulphuric acid, give any reaction with a salt of baryta, except when combined with a base. This is on account of the sulphite of baryta—unlike the sulphate—being soluble in free acid. When sulphuric acid is added to a salt of baryta, sulphate of baryta is formed, and the acid with which the baryta was previously combined is set free. But this acid can exert little or no action on the sulphate of baryta. Now, on adding sulphurous acid to a salt of baryta, the sulphite of baryta would dissolve in the acid set free, and which was previously combined with the baryta. But in the case of a salt having sulphurous acid in its composition, this does not occur. No acid is set free to exert a solvent action. For instance, if to a solution of chloride of barium is added a solution of sulphite of soda, a white precipitate of sulphite of baryta will be produced—

Supposing it to have been doubtful whether the salt employed was a sulphite or a sulphate, one can now determine the point by the addition of an acid, say

hydrochloric acid. Sulphite of baryta being soluble in this acid, the precipitate will disappear if the salt was a sulphite; if the precipitate is persistent, a sulphate is indicated. Of course, both may be present.

An old specimen of sulphite is sure to contain a quantity of sulphate, formed by oxidation, even though pure originally. To determine absolutely the presence or absence of sulphurous acid in a body, it is only necessary to dissolve it in hydrochloric acid, if solid, or if a liquid, make it acid to the same extent, and add a few scraps of zinc, such as is used in the production of hydrogen gas. If the body under examination contain sulphurous acid, the hydrogen going off will be accompanied by sulphuretted hydrogen, which may be detected by the smell, or by its blackening paper dipped in a solution of a lead salt. This test will discover very minute quantities of sulphurous acid. Such is its delicacy that sulphurous acid may be detected in much of the commercial hydrochloric acid; it arises from the action of the strong sulphuric acid on the iron decomposing vessel employed. The reaction may be explained as follows, leaving out the hydrochloric acid:—

One method of estimating sulphurous acid has been given, but the ordinary method is to convert it into sulphuric acid, and then proceed in the manner followed in the estimation of that acid. This may be effected by several oxidizing bodies. It is sometimes recommended to employ nitric acid, but there is a chance of error by doing so, inasmuch as a quantity of the sulphurous acid may escape whilst heating it. Perhaps the best method is to pass through the sulphurous acid or the sulphite to be analyzed a current of chlorine until the liquid smells of the latter gas, placing it on a sand bath until all smell has disappeared, then precipitate with a salt of baryta, collect, wash, ignite, *et cetera*, exactly as indicated under the head SULPHURIC ACID.

Sulphurous acid forms, with bases, a series of salts called sulphites, one of which has been already mentioned, the sulphite of soda. These sulphites have been shown by the Editor to bear a strong resemblance to carbonates, being also isomorphous with the latter salts. The following list proves the analogy:—

Sulphites.	Carbonates.
KO, SO ₂ + 2 HO	KO, CO ₂ + 2 HO
KO, SO ₂ + HO, SO ₂	KO, CO ₂ + HO, CO ₂
NaO, SO ₂ + 10 HO	NaO, CO ₂ + 10 HO
NaO, SO ₂ + HO, SO ₂	NaO, CO ₂ + HO, CO ₂
NaO, SO ₂ + HO, SO ₂ + 8 HO	NaO, CO ₂ + HO, CO ₂ + 8 HO
BaO, SO ₂	BaO, CO ₂
SrO, SO ₂	SrO, CO ₂
MgO, SO ₂ + 3 HO	MgO, CO ₂ + 3 HO
MnO, SO ₂ + 2 HO	MnO, CO ₂ + 2 HO
PbO, SO ₂	PbO, CO ₂
AgO, SO ₂	AgO, CO ₂

Sulphite of soda is the only salt—with the exception of a mixed sulphite of lime and magnesia—which is manufactured on a large scale. Sulphite of soda is made by passing a stream of sulphurous acid gas through a solution of carbonate of soda; the carbonic acid is displaced, and sulphite of soda is formed. On the large scale, the same method as is pursued in the

manufacture of bicarbonate may be followed for the production of the sulphite. A chamber or suitable large vessel is so constructed with appliances that a stream of sulphurous acid from burning sulphur may be drawn through. This chamber or vessel is filled with crystals of carbonate of soda; the stream of sulphurous acid in its passage through the interstices of the mass is taken up, carbonic acid being evolved. The passage of the gas must be continued until a sample taken out of the chamber, on being dissolved, has an acid reaction with litmus paper. The mass of what was originally carbonate of soda has now become a mixture of sulphite and bisulphite of soda. This is now dissolved in water, and brought to the boiling point; a solution of carbonate of soda must now be added, until the last addition causes no evolution of carbonic acid; the whole is now brought to the state of neutral sulphite; and after standing to deposit any mechanical impurities may be run off into a suitable vessel to crystallize.

The sulphites of potassa and ammonia may be prepared in a similar manner to that of soda, by passing sulphurous acid through a solution of the alkalies or their carbonates.

The sulphites of the alkaline earths are prepared either by exposing the moistened, or better, the hydrated oxides, to gaseous sulphurous acid, when this gas is absorbed; or the oxides or carbonates may be suspended in water, and a stream of sulphurous acid passed through; or they may be produced by double decomposition from a soluble alkaline sulphite, and a chloride of the earthy metal. These sulphites are all more or less nearly insoluble in water and alcohol, but are rendered more soluble by an excess of sulphurous acid, in this respect resembling the carbonates. The only practical purpose to which any of these earthy sulphites have been applied, is as disinfectants. For this purpose, a mixture of the sulphites of lime and magnesia is used. Mr. M'DOUGALL seems to have a method of producing sulphites much more readily than any other maker.

The sulphites of the metals proper, such as iron, zinc, lead, bismuth, *et cetera*, are produced by analogous processes; they, like the earthy sulphites, are more soluble in a solution of sulphurous acid than in pure water.

SULPHURIC ACID—*acid sulphurique*, French; *schwefelsäure*, German—is the most stable and the best known oxide of sulphur. It appears to have been known from very early times. BRANDE, in speaking of it, says that the honor of its discovery is due to BASIL VALENTINE. He frequently mentions it and its mode of preparation; and PARACELUSUS, and the authors who immediately followed, talk of it as well known and in common use, though it is probable that it bore a high price, and was but scantily supplied by a few awkward and unintelligent operators. But KOPP shows evidently that VINCENTIUS DE BEAUVAIS had an idea of the substance obtained by distilling alum. BOYLE first recognized in it a relation to sulphur. MAYOW pointed it out with great clearness, but he was far before his time in penetration. STAHL believed sulphur to consist of sulphuric acid and phlogiston, a theory in conformity with the rest of his system.

LAVOISIER showed the formation of acid by sulphur taking up oxygen, but it had been made by burning sulphur in the air, at least since the time of LEMERY and Dr. WARD. Sulphuric acid exists, as free acid, in two states, liquid and solid—the liquid being a combination of dry acid and water. The right of the dry body to be called sulphuric acid is doubted, as it exhibits no acid characters until combined or mixed with water. The character of the acid is sufficiently shown in the reactions of the monohydrated sulphuric acid— SO_3HO —or the purified oil of vitriol. This body is a heavy fluid, above three-fourths heavier than water. It flows when poured from one vessel to another, in a heavy, smooth, *oily* stream. This oily appearance has, doubtless, given it its name; and although this appellation, oil of vitriol, has been much ridiculed, it cannot be disputed that it is very expressive, and serves well to distinguish the strong vitriol from the dilute acid, which bubbles like water when poured. Oil of vitriol has a strong attraction for water, so much so that a bottle containing it, if left open, rapidly attracts moisture from the air, becoming itself much weaker. This property is often taken advantage of in analytical operations. When a stream of dry gas is needed, it is simply requisite to pass it through strong sulphuric acid, or through a wide tube filled with fragments of coke or pumice-stone saturated with the acid. This is a very effectual mode of drying a gas. It is not applicable to certain gases, between which and the sulphuric acid a reaction might take place. In the simple and elegant apparatus, devised by FRESSENIUS and WILL, for the estimation of carbonic acid, sulphuric acid is employed for the purpose of desiccating the carbonic acid before it emerges from the apparatus. It has been stated that sulphuric acid possesses the property of absorbing carbonic acid, and that consequently the operations in which its drying property has been taken advantage of cannot be correct. This, again, has been refuted; and, inasmuch as most chemists are in the habit of using this apparatus, it would appear to be tacitly allowed that if any error from this source does exist, it is so small as to be of no consequence.

This attraction of sulphuric acid for water also brings about some curious decompositions with organic bodies. For instance, if any of that class of bodies, such as sugar, starch, *et cetera*, which contain carbon, hydrogen, and oxygen, in such proportions that, for the sake of simplicity, they may be considered as being composed of carbon and water, be mixed with strong sulphuric acid, and heated, a black mass will be obtained; and if this mass be thoroughly washed with water, so as to remove every trace of sulphuric acid, it will be found to be pure carbon, the whole of the elements of water having been removed. So effectual is the process, that the principle has been proposed as a method of obtaining peat charcoal without the ordinary charring process. This charcoal is then washed and dried. To this same property is due the occasional brown color of commercial vitriol. If particles of organic matter fall into it, a portion of their hydrogen and oxygen is abstracted, forming a humus-like body, which, dissolving in the vitriol, colors it. This attraction for

water seems to be the principle by which it acts upon the skin, and animal and vegetal matter generally. The density of this monohydrated acid is 1·850, and it boils at a temperature of 620°. Its boiling point diminishes with its density. The strong acid is perfectly volatile, and thus capable of being distilled. It freezes at a temperature of 29°, yielding often six-sided prisms of a tabular form.

This acid has the power of supplanting or displacing almost every other acid known, so great is its affinity for bases. It produces great heat when mixed with water, the compound becoming denser than the mean of the two liquids. If equal volumes of strong sulphuric acid and water be mixed, and then allowed to cool, it will be found that the resulting liquid will not make up the original two volumes; it now occupies less space, contraction having taken place. During this contraction a portion of the latent heat of the water has been given off. PARKES made a series of experiments on this matter, the results of which are given in the following table:—

HEAT PRODUCED BY THE ADMIXTURE OF SULPHURIC ACID WITH WATER, TEN POUNDS OF SULPHURIC ACID BEING USED IN EACH EXPERIMENT.

Sulphuric acid in pounds.	Temperature of the mixture in degrees of Fahrenheit.
1	78°
2	100
3	110
4	128
5	138
6	144

But FAYRE and SILBERMANN have lately examined the question more thoroughly, and shown that the following amount of heat is given out:—

HEAT EVOLVED BY MIXING $\text{SO}_3 \text{ HO}$ WITH WATER.

Atom of water.	Heat units.	Differences.
With the first $\frac{1}{8}$	94·0	0·6
second $\frac{1}{8}$	88·0	
With the first $\frac{1}{4}$	18·8	1·6
second $\frac{1}{4}$	17·2	
With the first $\frac{1}{2}$	36·7	8·4
second $\frac{1}{2}$	28·3	
Atoms of water.		
1	64·7	29·9
2	94·6	17·3
3	111·9	10·3
4	122·2	8·5
5	130·7	5·5
6	136·2	4·4
7	141·8	3·3
8	145·1	3·4
9	148·8	0·0
10	148·4	0·0
20	148·6	

When four of the monohydrate are mixed with one of water by weight the temperature rises to 300°.

GRAHAM gives the following list of the hydrates of sulphuric acid—

Nordhausen sulphuric acid,	= $\text{HO}, 2 \text{ SO}_3$
Sulphuric acid, specific gravity, 1·850,	= HO, SO_3
“ “ 1·78,	= $\text{HO}, \text{SO}_3 + \text{HO}$
“ “ 1·632,	= $\text{HO}, \text{SO}_3 + 2 \text{ HO}$

The third hydrate in the above list corresponds nearly to the commercial brown oil of vitriol, the density of this latter being 1·758. It is formed by heating a dilute acid to 400°. Its properties are almost identical with those of the monohydrate. It has the property of solidifying at the temperature of melting ice, or a little above this point. It is no uncommon circumstance for a sulphuric acid manufacturer to find a carboy of brown vitriol converted almost into a mass of crystals, if exposed to the cold in frosty weather. These crystals are the well-defined hydrate in question. This crystallization has been proposed as a method of obtaining pure sulphuric acid, as will be seen hereafter. Little seems to be known of the lower hydrate. It is formed by heating a dilute acid at 212°. This amount of acid and water causes the greatest condensation of volume.

Neither dry nor fuming acid can be obtained by the ordinary mode of concentration, it being impossible to drive off the last equivalent of water. Dry acid may be obtained by distilling the Nordhausen acid— $\text{HO}, 2 \text{ SO}_3$. But Nordhausen acid is not now a common commercial product; it is often necessary for the operator to make his own. This may be done either by distilling the protosulphate of iron or the sesquisulphate, artificially prepared; bisulphate of potassa or soda may be also used. This latter salt is the cheapest, and perhaps the most convenient. It may be procured by heating one equivalent of common salt in a crucible with two equivalents of sulphuric acid, taking care to operate under a chimney, or in some situation where the hydrochloric acid fumes will be carried away quickly. When gas has ceased to be evolved from the mixture, the residue must be heated to a low red-heat, in order to drive off as much water as possible. The fused salt must be removed from the crucible and allowed to cool. This may be done by pouring it out into an iron dish, or other convenient vessel. When cold, it must be broken up, when it is ready for the next operation. Or, instead of this, the bisulphate of soda or potassa left in the retorts, when procuring nitric acid, may be preserved for the same purpose. Porcelain retorts being very expensive, it is well to substitute, if possible, some cheaper piece of apparatus. For this purpose an ordinary brassfounder's crucible may be employed; a lid may be formed out of a piece of ordinary fire-tile—this lid has a hole cut through, into which is inserted a piece of glass tube to carry off the vapor. The arrangement is shown in Fig. 571. To commence, a piece of brick is first laid on the bars of the ordinary laboratory furnace; on this the crucible is placed; this is filled with the broken pieces of bisulphate; the lid is luted on with clay, and the tube luted into the lid. A fire is lighted around the crucible, and this is gradually increased in power, until at length

distillation commences. Weak acid at first comes over—this is emptied out of the receiving flask; eventually the retort or crucible begins to attain a good red-heat; drops of strong acid fall, and hiss as they touch the weaker acid in the flask. The flask is now

Fig. 571.

finally emptied of its contents, and replaced, the acid which now comes over being fuming acid, white vapors pour through the glass tube at a rapid pace, a portion condensing there, and a portion in the flask. The flask should be a thin one, and is all the better for being placed in a basin of cold water. After a time vapors cease to appear, and the operation is at an end. The glass tube should now be carefully taken away, as also the lid of the crucible, and the fused or softened mass, forming the contents of the latter, should be removed by means of an iron scoop. This done, the crucible should be allowed to cool slowly; when cold enough, it may be filled again, and the foregoing operation repeated. With care, a crucible will last three or four operations. The neutral sulphate may be reconverted into bisulphate, to be again employed.

The fuming acid so obtained gives off white vapors. These white fumes are dry acid— SO_3 —vapor, combining with the moisture of the atmosphere. It makes a hissing noise when poured into water, very like the noise made when red-hot iron is plunged into a liquid. This acid is employed in gas analysis, on account of its possessing the power of absorbing certain hydrocarbons. For this purpose a piece of coke is wetted with the fuming acid and passed into the gas to be analyzed, standing in a graduated tube over mercury. To obtain the dry acid it is necessary to submit the fuming acid to distillation at a gentle heat. For this purpose a glass retort is partially filled with the fuming acid, the neck of the retort is inserted into a flask, placed in cold water, a gentle heat is applied to the retort, when the dry acid begins to come over. It condenses in solid fibres like asbestos, which are tenacious, and may be moulded by the fingers like wax. Its density at 68° is 1.970; at 77° it assumes the liquid state; and a little above that temperature it enters into ebullition. If a little of this *anhydrous* acid be placed on a slip of dry litmus paper no reddening results—coloration not taking place until moisture has been absorbed.

Manufacture of Sulphuric Acid.—The principle involved in the mode of working adopted by Dr. ROEBUCK, who may be considered the first inventor or improver, still continues in vitriol manufactories; in fact, from that time may be dated the actual rise of the sulphuric acid manufacture.

The earlier process, and, according to many authorities, the one still followed in a few places where natural advantages render it profitable, is one already alluded to, and which consists in distilling or driving off by intense heat the sulphuric acid from protosulphate of iron. This salt is dried and placed in fireproof retorts, which are built in suitable furnaces. Proper receivers are connected with them. These retorts are charged, and heat applied, until they become sufficiently hot. The sulphuric acid is driven off and condenses in the receivers, while oxide of iron is left in the retort. The following description, extracted from KNAPP's excellent work, will give a good idea of the process as followed at Radnitz:—The material operated upon is the mother liquor from the manufacture of alum. This contains a large quantity of protosulphate of iron. These mother liquors are first evaporated to a dry state, and then roasted at a gentle heat. During this latter roasting a considerable quantity of oxygen is absorbed, the protosulphate passing partially into basic persulphate of iron. These operations are conducted on the spot where the alum liquors are to be had. This roasted product, which is called *vitriolstein*, is sent to Radnitz for conversion into fuming oil of vitriol. This process consists in the dry distillation of the vitriolstein. The pots in which the distillation is effected are constructed of refractory stoneware, and after being baked in a kiln upon the premises, are about nine inches long, two and a half inches in diameter at the bottom, four and a quarter at the middle, and three inches at the mouth; they are about four-tenths of an inch thick in the sides. Before being used they are covered with a lute, or luting material, which is easily fritted by the action of the fire. The receivers are of much the same shape, but are longer and narrower at the mouth. The upper row in the furnace is occupied by a single range of pots twenty-eight inches in length. The gallery furnace for the reception of the pots is rectangular in section, and is composed of two parts essentially distinct. The lower part is built of massive masonry, enclosing the ash-pit and the grate, which extends the whole length under the range of pots; the upper part consists of two vertical walls of perforated brickwork, which form the sides of the furnace and support the pots. This latter portion demands frequent repair. Fig. 572 represents a front vertical section. It incloses four tiers of the smaller sized pots, arranged with their bottoms in contact, and an upper tier of long pots, which extend from one side of the furnace to the other, and are open at both ends. The whole, therefore, contains two hundred and eighty-eight pots—thirty-two large, and two hundred and fifty-six small. The long sides of the furnace are divided into squares by vertical and horizontal bricks of the same dimensions, and four pots are placed in each square, separated from each other by small bricks, the interstices being luted with refractory clay. The arch of the furnace is constructed of flat bricks, simply placed alongside each other, and cut sloping at their extremities, to allow the flame to pass. A small chimney is sometimes built to the furnace, but it is more frequently without. The pots are charged with the vitriolstein, previously broken up with a hammer, by means of a

semicylindrical spoon, each pot receiving two spoonfuls. The coal for the first charge is then ignited below the grate, and is thrown upon the grate at the expiration

Fig. 572.

of about an hour or an hour and a half; the fire being carefully regulated by opening or shutting the doors. At the end of four hours the lower tier of pots is brought to a dark-red heat. The receivers are successively introduced into the pots and luted, those of the second layer resting immediately upon the first, and a wooden support being introduced between the second, third, and so on. The receivers are slightly inclined, and a small quantity of water is placed in each. This is sufficient to receive the acid from four successive distillations, after which it is in the state of concentration required in commerce. The fire is gradually increased, and after from thirty to thirty-six hours no more acid is evolved from the upper tier of pots, and the distillation is finished. The whole is then allowed to cool for twelve hours, and the receivers being removed the colcothar is taken from the pots. This contains about six and a half per cent. sulphate of lime, and amounts to about thirty or thirty-five per cent. of the vitriolstein employed.

The pots are now examined by the sound which they emit when struck. The broken ones are removed, and being replaced by fresh pots, the distillation is recommenced.

Each operation lasts about forty-eight hours, and three are completed in a week. From forty-seven to fifty per cent. of the vitriolstein is obtained in fuming sulphuric acid; five parts of coal are consumed for one part of vitriolstein distilled. About thirty pots and three receivers are replaced after each distillation, which is equivalent to 10·42 and 1·04 per cent. respectively.

Although such a mode of manufacture may be capable of being followed in some localities, yet it is far from possessing the general adaptability of the ordinary process. From the above description there appears to be little loss, except from accidental leakage or the breaking of a pot; but as the process is described by many, or in fact the greater proportion of writers, simply dry protosulphate of iron is employed— FeO SO^3 —not as in the method just described, sesquisulphate— $\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3$ —or rather a basic persulphate. The employment of one or the other must make a considerable

difference in the amount of product obtained, for if any protosulphate of iron be employed, only one half of the sulphuric acid contained in it will be obtained as *sulphuric acid*, the rest passing off as sulphurous acid. The following is the reaction:—

Two equivalents of protosulphate of iron are decomposed into one equivalent of sesquioxide, one of sulphuric acid, and one of sulphurous acid; one of the equivalents of sulphuric acid has parted with one of its equivalents of oxygen, in order that the two equivalents of protoxide of iron might become sesquioxide. This equivalent of sulphurous acid is said to escape through the joints of the apparatus; if so, and there does not appear to be any doubt of this being the fact, inasmuch as no other provision appears to have been made for its exit, one may naturally conclude that sulphuric acid vapor must escape at the same time.

Such was the method pursued for procuring sulphuric acid for some centuries. The next process—a modification of which remains in use to this day—consisted in converting sulphur by stages of oxidation into sulphuric acid. This differs materially from the process before described, in which acid already formed was simply separated from a combination; in the present case the operation commences with the prime element. The first step in this direction appears to have been the formation of sulphuric acid in small quantities by the combustion of sulphur in glass globes, moistened on the interior surface with water. It is true that under these circumstances a small quantity of sulphuric acid would be formed, but the amount would be very minute indeed; in fact, the combustion of sulphur in pure oxygen gives rise to little more than a trace. But a grand step was made in the right direction by the introduction of nitre in the manufacture. The use of sulphur and nitre together was said to have begun with LEFEVRE and LEMERY. Dr. WARD had the monopoly of it long in this country, and best knew how to manage the process. Instead of sulphur *per se*, a mixture of sulphur and nitre was made, and set fire to in or under a bell glass; by this proceeding a much greater quantity of sulphuric acid was obtained. It can easily be imagined, that even the most successful experiment could furnish only a small quantity of acid, on account of the very limited size of the apparatus. This must strike an observer when he contrasts in his own mind the largest jar or globe that could be blown, even now, with one of the vitriol chambers of the present time. But this difficulty of limited dimensions was surmounted by a Dr. ROEBUCK of Birmingham, who was the first to introduce leaden chambers, which he did as a substitute for the comparatively small globes; and as he was able to make them of any required size, a great relief must have been given to the manufacture. The manner of working was still precisely similar to that with the globe. The chamber had an entrance-door, which could be luted tight; this was opened, and a charge, consisting of a mixture as before of sulphur and nitre, was put on a proper stand placed to receive it in the chamber. According to some authors this was a sort of carriage, which could be pulled towards the door to receive the

charge, and then after ignition pushed towards the centre of the chamber; but it is difficult to conceive that this is true, as it would not be easy to find material of which to construct the wheels and other parts of such a machine, when it is considered that the floor of the chamber was covered with acid to the depth of several inches. It is certain that the proper charge was placed on a stand in the interior of the chamber; this was ignited, and the door was then properly fastened and luted. After a certain time had elapsed the door was again opened, and the residual gas or gases allowed to escape. This was repeated again and again, until the water with which the floor of the chamber was covered had absorbed sufficient of the acid, when it was run off and concentrated. Authors speak of a collapse of the sides of the chamber occurring, owing to the partial vacuum produced by the absorption of the oxygen of the contained air. But it can be scarcely believed that this accident could have occurred often, since it is hardly conceivable that practitioners of the chemical art at that time could have been ignorant of the fact that a very simple arrangement of a water-valve opening inwards would have remedied this.

This process, then, was the one followed by Dr. ROEBUCK, and such in principle it remains down to the present day; and had it possessed the advantage of a later invention, *videlicet*, the introduction of steam, it would no doubt have given an excellent result. Supposing there had been in the chamber twenty-four parts by weight of oxygen for every sixteen parts of sulphur introduced, watery vapor being also present in sufficient quantity, every particle of sulphur must have been converted into sulphuric acid, if sufficient time were allowed to elapse before the opening of the chamber door.

Having followed the manufacture to this point, one must now pass on to another step, from the intermittent to the continuous process, as practised at present. It is easy to see that had Dr. ROEBUCK burned his sulphur in a properly constructed apparatus, and introduced the resulting sulphurous acid into his chamber at one end, drawing off the residual gases at the other, he would have improved his method, and escaped many inconveniences.

If one views the gigantic scale in which this manufacture is carried on at the present day, by a TENNANT or a MUSPRATT, he must smile on looking back at the almost puny manner in which they operated in former times; but, then, add to their process the continuous system—the introduction of steam into the chambers by KESTNER, concentration in the platinum vessels, and GAY-LUSSAC's column for the recovery of the nitrous gas—and manufacturers have almost all that could be desired at present.

Much ingenuity has been expended in the construction of every piece of apparatus connected with the manufacture of vitriol. The ovens or burners, the chambers, and every part, have been tortured into a variety of forms, some of which would appear to have been devised in an idle moment, and constructed only to gratify a whim, or if any object has really been in view, it must have been imaginary. But in every manufactory where the process is understood, the difference,

except in little details, between the apparatus of to-day and that of twenty years ago, is very small. Improvement after improvement, which have turned out to be rather impediments, have been introduced, had their short reign, and disappeared, only to be succeeded by something else equally visionary. In fact, it would seem that the manufacture of sulphuric acid, though as extensively carried on as any business, yet seems to be the least understood; and the ignorance of some manufacturers appears to be only equalled by that of writers who, in their descriptions of the production of this acid, give figures of apparatus, and vaunt as improvements things which have been exploded for years. It is possible to find, in the works of eminent men, drawings of sets of apparatus for the production of sulphuric acid, *which never could possibly have worked one day*—some, in fact, could never have worked at all.

Production of the Sulphurous Acid.—This first step is effected by burning the sulphur in a close room or oven,

Fig. 573.

Fig. 574.

commonly called a burner. This burner is a simple erection of brickwork, with an arched roof, as shown in Figs. 573, 574, and 575. The size of the burner is regulated by that of the burner plate or iron flooring, and this latter by the quantity of sulphur proposed to be burned during seven days. The burner plate in the drawing is a rectangular iron, measuring eight feet by four feet. This burner plate is surrounded with a vertical edge or border, standing about an inch high; this border is at right angles to the plate on three sides, but on the fourth side, the one nearest to the door, it inclines outwards at an angle of about forty-five degrees—this is for the more conveniently raking out of the residual dirt and ashes left after the combustion

Fig. 575.

of the sulphur. The door of this burner is simply an iron plate, sliding in grooves in an iron framework, and is counterbalanced by a weight hanging at the end of a chain, which passes over pulleys.

As will be seen in the figure, the iron plate does not form the whole of the floor; still the sulphur is burned on it alone. The object of making the burner rather larger than the plate is to avoid, as much as possible, all risk of sublimation. To this end, also, there is a constant current of air passing beneath the burner plates and up a small chimney beside the burner. The opening through which the hot air escapes into this chimney is outlined in Fig. 575, below the burner plate. Four burners, such as this, with the burner plates of the size first mentioned, will easily convert into sulphurous acid one ton of sulphur per twenty-four hours. The quantity for each burner is divided into six portions, one of which is added every four hours.

Burners or ovens have been constructed of iron, sometimes with double sides, so as to include a sheet of air between the two plates. By this means the burners could be kept at almost any desired temperature; an arrangement could be made for causing a circulation of air if the burner should get too hot, or, on the contrary, should they get too cold, this air could be kept stagnant, and being a very bad conductor of heat, the burner would be allowed to rise to the desired temperature. It may be remarked here, that a burner should be kept so hot that each charge of sulphur, as thrown in, will ignite without any fire or heat being applied.

Iron ovens or burners have, however, almost disappeared, as they last a very short time. They gradually corrode, break into holes, and shortly become useless.

Some years ago a patent was taken out for a burner, the peculiar feature of which was its economizing, and converting to a useful purpose, the heat given off by the burning sulphur. The apparatus was very simple. It consisted of an ordinary two-flued steam boiler, for the usual fire-place of which was substituted a burner plate on which to burn sulphur. It was anticipated that by this means sufficient steam would be generated to supply the chambers. Whether it answered the desired end or not is not very clear; but from the fact that none appear to be in operation, it may be inferred that, if in use at all, it is not generally successful. In fact it is very probable that the action of the acid gases upon it would speedily destroy it, as it does the iron burners.

Combustion of Iron Pyrites.—Sulphur, *per se*, is not the only source of sulphurous acid for sulphuric acid. About the year 1835 the then King of Sicily thought fit to impose such a heavy duty on all sulphur exported from his kingdom, that the price of this article rose to an unprecedented height. It is said that at this crisis Dr. THOMAS THOMSON proposed the employment of the iron pyrites, with which different parts of this kingdom abound, as a source of sulphur. PARNELL states that Mr. HILL of Deptford was the first to employ this mineral, for the use of which he took out a patent in 1818. Since that time pyrites has come into very general use amongst one class of sulphuric acid manufacturers. The great objection to the use of pyrites lies in its containing a considerable amount of arsenic. This renders the vitriol objectionable for certain purposes, but this impurity does not prevent

its being used by the alkali manufacturers. A manufacturer of vitriol for sale would, were he to use pyrites, very likely have a quantity of his acid returned to him, and he would presently have to stop his manufactory. Not so the soda manufacturer; he is his own vitriol consumer—he uses all the acid he makes for the decomposition of common salt in the first step of soda-making. In his case the arsenic does not interfere in the least, it passes off as chloride of arsenic— As Cl_3 —with the hydrochloric acid gas, and condenses into a liquid state with this latter body. Again, most manufacturers of soda are also manufacturers of chloride of lime. In this case they use up their own hydrochloric acid, employing it for the production of chlorine, which is absorbed by hydrate of lime, forming the bleaching powder of commerce. If a little of the arsenic should pass over with the chlorine, it would be absorbed by the lime, forming an insoluble compound, arseniate of lime, which would fall out, with other useless matters, when the bleacher came to make his solution. The greater portion of the arsenic would remain with the chloride of manganese, and as at present this is a useless product; it is run into the nearest gutter or sewer.

The burning of pyrites is not quite so simple a matter as the burning of sulphur, as a red heat is required. Two varieties of pyrites are ordinarily met with. One kind, of which large quantities are to be found in Wicklow, Ireland, and is imported into this country, to a considerable extent, for the use of sulphuric acid manufacturers, has the crystalline form of a cube, and is of a bronze-yellow color, very hard, so much so as to strike fire with steel. The following is the composition of a specimen, on the authority of R. D. THOMSON—

	Centesimally.
Sulphur,	47.41
Iron,	41.78
Copper,	1.93
Arsenic,	2.11
Silica,	3.93
Zinc,	2.00
Insoluble matter,	1.43

This specimen is of a much richer kind than that usually obtained from this source. The proportion of sulphur very rarely exceeds thirty per cent. This ore contains protosulphide of iron in considerable quantity. The other variety of pyrites occurs in coal beds, and, in fact, is commonly known as coal brasses, fragments and seams of this mineral, may often be seen in coal, and, from their metallic and brassy appearance, have often misled the ignorant into thinking them of much greater value than they really are. According to the just quoted authority, they have the following composition:—

	Per cent.
Sulphur,	53.35
Iron,	45.07
Manganese,	0.70
Silica,	0.80
Loss,	1.18
	100.00

A variety of pyrites, known in the trade as Spanish pyrites, has of late been much employed. This is much richer in copper than the Wicklow species. On the introduction of this mineral, it was usual for the sulphuric acid manufacturer to engage to return the

spent or burnt material, for the purpose of having the copper extracted.

The general formula of either variety, when free from impurity, is Fe S_2 , that is, one equivalent of iron combined with two equivalents of sulphur, the chemical name of this compound being bisulphide of iron.

This mineral, when heated red hot, with access of oxygen, speedily loses the second equivalent of sulphur, being reduced to a simple or protosulphide— Fe S —the evolved sulphur being converted into sulphurous acid. If these favorable conditions are continued for a sufficient length of time, the second equivalent also becomes converted into sulphurous acid, sesquioxide of iron remaining. The whole decomposition may be represented as follows—

As may be imagined, the ordinary burner, as used for sulphur alone, lately described, is not adapted to burn pyrites; a burner of peculiar construction is required. The burner for this purpose is, in general structure, not unlike a lime-kiln. In the case of burning sulphur itself, the object is to spread a layer on a flat plate, so that, when fused and burning, it exposes a large surface for the current of air to sweep over; this is necessary on account of the fusion of the sulphur. But pyrites does not fuse except at a very high heat. The pieces retain their shape; and as it is imperative that they shall attain a red heat, it is necessary to burn them in such a manner that a mass of them can be kept together.

The structure of a pyrites kiln is shown in Figs. 576 and 577. In Fig. 577 the pyrites is shown as inclosed on two sides by two sloping walls, the back and front walls being vertical. The mass of pyrites rests on

for the purpose of arresting, as much as possible, the passage of arsenical vapors. The arsenic falling in a solid state is removed from time to time. Fig. 576 is a view of one of these kilns looking in another direction, endwise; *a* is the charging door through which fresh supplies of the mineral are thrown in at stated intervals. This door is kept closed, except for this purpose. At *b* another opening exists, but this is usually closed temporarily with bricks—it is only occasionally used. Sometimes the combustion goes on at a rate so rapid that the pyrites becomes fritted, or enters into a semifused state. Sometimes the whole mass gets fused together by its points of contact. In such a case the brick closure is removed for the purpose of introducing a crowbar, or other such instrument, in order to break up the mass or create a passage through. The coal pyrites is much more liable to this mishap than the Wicklow variety, partly on account of the bisulphide contained in it being actually rather more fusible, and partly because the coal brasses contain a certain amount of bituminous matter, which, in burning, raises the heat of the whole mass to a higher point than the Wicklow kind ever attains. The orifices, *c* and *d*, are those through which the sulphurous acid passes either into the next kiln or into the general passage.

It is not usual to see an isolated single pyrites kiln; there are often a number at work. Two are placed at the back of those shown in the drawing, forming a solid square. This answers a double purpose—it economizes brick and iron, and conserves the heat.

When commencing to burn, it is necessary to make a fire of coal or coke within the burners, having previously closed up the passage or entrance into the chamber, and opened one into the outer air. This fire heats up the sides, *et cetera*, of the kiln, high enough to ignite the pyrites when thrown in. The first few charges of pyrites are often mixed with coke to assist the combustion, until the whole mass has attained a red heat throughout. The carbonic acid resulting from this can do no harm.

The residual mass left after burning, and which consists principally of sesquioxide of iron mixed with more or less protosulphide, was at one time rather an annoyance than of any value to the manufacturer; but at the present time many of them have erected furnaces for the express purpose of extracting the small per centage of copper which it contains.

The quantity of sulphuric acid obtained from a given weight of pyrites of course cannot be as much as from sulphur, inasmuch as pyrites,

iron bars in the same manner as an ordinary coal fire, the air rushes up from what, in the case of an ordinary furnace, would be the ash-pit, and wends its way through the crevices and interstices of the mass to feed the combustion. The sulphurous acid from the first kiln passes over the next in the direction of the arrows, the gases from both flowing into the general passage, *a*, leading to the chamber. This general passage is often made of a considerable length, usually of from thirty to forty feet. This extreme length is

to take a general average, will not contain more than forty per cent. of sulphur; as a rule, a corresponding amount of sulphuric acid is not obtained from it. Much care and attention is required to burn pyrites well. It is no uncommon thing to find, on examining the waste pyrites heap of a manufacturer, that a great quantity has been removed little more than half burned. On breaking a lump a core or kernel of raw mineral may often be found; whereas well burned pyrites should not contain more than two and a half to

Fig. 576.

Fig. 577.

three per cent. of sulphur. Any amount more than this is in fact so much material thrown away.

General Construction of the Vitriol Chamber.—Having described the preliminary steps, the Editor now passes on to the chambers themselves. These have undergone many modifications. The chamber, as generally constructed, is simply a large room with leaden walls. A portion of one is shown in Fig. 578. These walls are generally formed of what is technically termed five-pound lead—that is, sheet lead weighing five pounds

per square foot—which walls are held up by a suitable framework of wood, to which they are fastened by what are called straps. These straps are pieces of lead, varying in number and size according to the dimension of the chamber. They are soldered or fastened by one edge to the sheet or sheets of lead forming the chamber side. The outer edge is pulled out over the wooden cross bar, and there nailed as shown at *a*, Fig. 578. The joints of the sheets of lead forming the chamber were formerly soldered with ordinary solder ;

Fig. 578.

but this entailed a long series of annoyances in consequence of the action of the acid on the solder. The chamber leaked perpetually, and great inconvenience resulted. Eventually the expedient of welding was hit upon. This consisted in rolling the two edges of the sheets together and beating this flat; but this at last gave way to the method at present followed, *videlicet*, fusing the two edges of the sheet together by means of the oxyhydrogen blowpipe. For this purpose an apparatus is constructed which furnishes a constant and pretty strong current of hydrogen gas. This when mixed with a proper amount of atmospherical air projected from a pair of bellows furnishes the blowpipe. To use it the workman proceeds as follows :—He lays the edges of the two sheets together as closely as possible ; every particle of dirt and oxidized or tarnished surface is scraped off ; the flame is now applied in a peculiar manner, acquired by practice, and the two edges are joined together ; thus making a solid joint of pure lead, as incapable of being acted upon as any part of the sheet. The plumbers who undertake the erection of these chambers are able to join two sheets of lead together even when the joint is in a vertical direction ; but as it is rather a difficult and tedious business, they contrive to do as much as possible of it in a horizontal direction.

No rule can be given for the shape or dimensions of a chamber. Manufacturers are guided partly by convenience, partly by the size of the lead sheets procurable, and partly by a desire to have as much space as

possible included in the chambers with the least expenditure of lead. It is with this view that many chambers of vast size, and in shape as near as possible a cube, are being built. Of course, the nearer a chamber approaches a cube in shape, the more absolute chamber room is gained for the lead expended. It is now becoming usual to build chambers of enormous size, with the view of economizing lead. In order that a comparison may be drawn between the old mode of manufacturing sulphuric acid, and the way of proceeding at the present time, some dimensions of chambers at present in work may be given ; but it is generally admitted that the best produce is obtained from a series of small chambers, in which one would burn equal to a ton of sulphur *per diem*.

Mr. SCHOLEFIELD, chemical manufacturer, of Bradford, near Manchester, possesses a chamber of the following dimensions—seventy feet long, thirty-five feet wide, and thirty-five feet high ; thus possessing the enormous space of eighty-five thousand, seven hundred and fifty cubic feet. The same gentleman has also another large chamber, rather less than this one. It is forty feet long, thirty-five feet wide, and twenty-five feet high. Mr. SPENCE, also, of Newton Heath, alum manufacturer, has a fine chamber of the following dimensions : seventy-five feet long, forty feet wide, and forty feet high ; containing, of course, one hundred and twenty thousand cubic feet of internal space.

These are not the only ones—chambers of similar

magnificent dimensions are being built in many parts of Lancashire; and at Flint, North Wales, at the gigantic factory of MUSPRATT BROTHERS and HUNTLEY, chambers are of the following dimensions: one hundred and forty feet in length, twenty-four and a half feet wide, and nineteen and a half feet high; the internal space being therefore, sixty-six thousand, eight hundred and eighty-five feet. The above instances are singled out as illustrations of the chambers of the present day.

It will be easily understood that the size of the chamber, or rather the chamber space, must bear some relation to the sulphur burned. Some manufacturers are more successful than others in this respect, being able to produce more vitriol in rather less space than others, probably owing to some variation in working. In a Lancashire work, possessing chamber space to the extent of one hundred and twenty-four thousand, two hundred and sixty-eight cubic feet, they are able to convert eighteen tons of sulphur into sulphuric acid per seven days, the chambers being arranged in the form shown in Fig. 580, to be referred to hereafter. It may be well to notice, that when working with plenty of chamber space less nitre is needed. The reason will be seen when the theory of the action in the chamber has been studied.

As a general illustration of the construction or principle of a sulphuric acid chamber, it may be said to resemble a bell-jar, as used in the ordinary manner for gas experiments. In this case the bottom resembles a large square basin, into which the chamber appears to have been inverted, like the before-mentioned bell-jar in a saucer of water. This is shown in Fig. 578. The height of this basin edge, or turn-up, as it is technically termed, is about twelve inches. Into this, as in the figure, the side dips, and a light water lute joint is produced. By pushing the chamber side a little inwards—as in Fig. 579—from the turn-up,

Fig. 579

a space is formed in which the shorter leg of a siphon can be put, for the purpose of drawing off the contents of the chamber as wanted.

It is seldom that one single chamber is worked by itself, at any work, unless it be a very small one. The usual plan is to work a greater or less number from one into another. An arrangement is figured in PAYEN's work, in which some five chambers are represented as forming a battery, the gases proceeding from

one to another through the whole series. But it is not usual to see such a number connected together. In this country, at least, the number is often limited to two or three chambers working into each other. This answers very well. A favorite arrangement is shown in Fig. 580, which represents three chambers connected together. The chamber, A, has one or two

Fig. 580.

burners attached to it; the same with chamber B. The gases generated in these ovens rise through a cast-iron stalk or chimney into A and B. The portions which escape condensation into these chambers, are conveyed through the passages shown in the drawing into C—the third chamber. If any residue remains it passes with the waste gases into the chimney, through the tube at the end.

Theory of the Production of Sulphuric Acid.—The production of sulphuric acid in the chambers is the result of a series of rather complicated reactions. It was sufficient for the old manufacturers to know, that certain bodies placed in certain relative positions produced sulphuric acid; but for the present day this is not sufficient. The reactions of the different gases and vapors on each other, have been repeatedly studied, and much difference of opinion exists on this head. The reactions are very curious and interesting, the chief being the remarkable and useful property of the nitrous constituent of the chamber gas—of acting as a carrier of oxygen to the sulphurous acid. Were nitric acid capable of yielding up at once the whole of its oxygen to the sulphurous acid, it would require eighty-five parts of nitrate of soda to furnish nitric acid sufficient to oxidize the sulphurous acid produced from eighty parts of sulphur, so as to convert it into sulphuric acid. But in practice one hundred parts of sulphur are converted into sulphuric acid with the aid of from five to ten parts, according to the way of working, of nitrate of soda. This is rather startling; but chemists have traced out the fact, that though atmospheric oxygen is itself incapable of at once combining with sulphurous acid, eventually it is from

this source that the extra oxygen is supplied. The reaction may be studied on the small scale by the aid of the apparatus, Fig. 581, which may for the purpose be considered a sulphuric acid chamber in miniature. This apparatus consists of a large flask or balloon. In

Fig. 581.

thus the action is to go on, the flask is to furnish sulphurous acid, while the Woulfe's bottle is for the production of nitric oxide by the action of nitric acid on slips of copper. Tubes from both these pieces of apparatus conduct the respective gases into the large globe, which globe has also two other tubes inserted through its perforated cork—one is for the purpose of introducing atmospheric air, while the other is the exit pipe for the residual gases, *et cetera*. The apparatus is set to work in the following manner:—A small quantity of water is introduced into the large globe. This is turned about until the sides have been wetted. Copper turnings are placed in the two-necked bottle and in the flask, and the whole apparatus is fitted together as shown in the drawing. An ounce or two of strong sulphuric acid is now poured on to the turnings in the flask, and heat applied; as explained under sulphurous acid, this gas begins to be evolved. When a steady stream begins to be given off, a quantity of commercial nitric acid, diluted with about half its bulk of water, is poured into the Woulfe's bottles through the tube funnel with which it is furnished. A stream of nitric oxide— NO_2 —begins to be evolved immediately. This, soon as it comes in contact with the air in the globe, takes up another equivalent of oxygen, becoming peroxide of nitrogen— NO_4 . A reaction now ensues between this and the sulphurous acid from the flask. The NO_4 combines with the SO_2 —sulphurous acid—forming, it is supposed, a compound having the following formula— $\text{NO}_2 \cdot 2 (\text{SO}_3 \cdot 2 \text{HO})$ —water being present; or to follow the decomposition—

This, added to another equivalent of sulphuric acid already formed, the product of a previous action, makes up the formula before given. This latter body makes its appearance as an icy crust on the sides of the globe. Join one of the two open tubes on to a gas holder, or aspirator, and cause a small current of air to be drawn or forced through, to replace the oxygen absorbed by the nitric oxide— NO_2 ; remove this when done, and join on a small retort, or flask containing boiling water;

and now drive a small jet of steam into the balloon. Immediately the steam enters, the frosted coating will melt off the sides and decompose, streams of acid will run down the sides of the globe, and the whole interior will become filled with red fumes. If thought proper, the experiment can be repeated; it is only necessary to throw in a fresh quantity of sulphurous acid. This will again decompose the peroxide of nitrogen, forming the same compound as before—thus the experiment can be gone over several times. In this experiment, it is generally supposed that one has in miniature the action of a chamber; but this is scarcely the exact truth, inasmuch as the circumstances, though very nearly, are not quite the same as on the large scale; and daily experience teaches, that a small difference of circumstances will sometimes produce a great difference in a reaction. In the vitriol chamber itself, all the necessary re-agents are present at the same time, so that it is not unreasonable to suppose that some variation from the above described experiment may take place.

Almost every chemist who has studied the subject, has taken a different view of the question; though all appear to concur in supposing that the formation of the crystalline compound precedes the formation of any sulphuric acid. On this account most ingenious theories have been broached, explanatory of the decomposition which ensues. All concur in the opinion that it is nitric oxide which is evolved when the crystals come in contact with the water. With a view to elucidate the subject, these crystals have been repeatedly analyzed, but the analyses differ much. Dr. THOMSON gave their composition as— $3 \text{SO}_2 + 2 \text{SO}_3 + \text{NO}_5 + \text{HO}$ —a scarcely probable combination. Dr. HENRY again, from his examination, considered them to be composed of— $5 (\text{SO}_3 \cdot \text{NO}_5) + 5 \text{HO}$ —a more likely supposition. The analysis of these crystals must always be a difficult matter. It is impossible to procure them absolutely pure; and even were they obtained pure, they are so very prone to decomposition, that it is almost as difficult to keep them so for the purpose of analysis.

The theory of the chamber reaction just given, and which first originated with CLEMENT and DESORMES, is the one held by many chemists, including KNAPP, who gives it in his *Technology*; but there are others who hold that the decomposition and recomposition of nitric acid is an essential part of the chamber reactions. Amongst these latter may be named PELIGOT, quoted by R. D. THOMSON. PELIGOT considers that there are four phases in the process. The first is the mutual reaction of sulphurous acid and nitric acid, the products being sulphuric acid and peroxide of nitrogen— $\text{SO}_2 + \text{NO}_5 = \text{SO}_3 + \text{NO}_4$. Two equivalents of this NO_4 combine, forming nitric acid and nitrous acid— $2 \text{NO}_4 = \text{NO}_5 + \text{NO}_3$. This nitrous acid again, under the influence of water, is decomposed into nitric acid and binoxide of nitrogen— $3 \text{NO}_3 = \text{NO}_5 + 2 \text{NO}_2$ —which two equivalents of binoxide of nitrogen unite with two equivalents of free oxygen, becoming once more peroxide of nitrogen, which eventually becomes nitric acid by a repetition of the last three decompositions just traced out. The nitric acid formed at these several

stages acts, of course, exactly as in the first instance. Nitric acid is very easily decomposed by sulphurous acid. This may be illustrated by wetting the interior of a bell-jar with nitric acid, then placing it over a capsule of burning sulphur, and setting on a tile or plate; in a few seconds the jar becomes filled with red fumes, the sulphurous acid having abstracted a portion of oxygen from the nitric acid, reducing it to peroxide of nitrogen.

It has thus been attempted to indicate a possible means of one portion of nitric acid or nitrous gas acting *ad infinitum*, converting an almost endless quantity of sulphurous acid into sulphuric acid, without being itself diminished. Notwithstanding the amount of study and labor bestowed on this question, it is doubtful whether chemists have arrived at more than an approximation to the actual reaction in the chamber. When the very changeable nature of all the bodies which there react upon each other is considered, one can scarcely hope to attain the actual truth. The explanations just given of the formation of sulphuric acid, though doubtless such as take place, are probably only two of many; it is likely that a variation in the action of these bodies on each other is perpetually taking place, as there is a deficiency or an excess of nitrous gas, more or less steam, a greater or less quantity of atmospheric air present, a higher or lower temperature, and many other causes may vary these changes; yet one has a tolerably clear view of the general mode of action. It is a general and wide-spread opinion, that the formation of the crystalline body invariably accompanies the formation of sulphuric acid; whereas in practice its appearance is only accidental. That these crystals should be constantly formed under the ordinary working condition of the chamber is almost impossible, when their great instability when in contact with water is considered, and, as in the atmosphere of a chamber properly worked, a great amount of aqueous vapor always exists, their formation is not very probable; for one can scarcely imagine that a body can be produced under such circumstances, that, were the same body ready formed to be so placed, it would be decomposed. Still, these explanations serve to show how it is possible for a small quantity of nitric acid or nitrous gas to convert a large quantity of sulphurous into sulphuric acid, acting as a carrier between the oxygen of the chamber and the sulphurous acid, constantly taking from one and immediately delivering up its plunder to the other. In order to understand the extent of this action, a previous statement must be remembered of the amount of sulphuric acid which a given weight of nitre could produce, were its oxidizing powers limited to the oxygen contained within itself. It is only from this view that the beauty of the chamber reaction is seen; and perhaps no other metamorphosis is, when looked at in a scientific point of view, so beautiful. It is the hinge and turning-point of the whole manufacture; for were it not possible to produce such a large amount of vitriol with the expenditure of such a small quantity of the most expensive ingredient, the commercial value of vitriol would of course be proportionally higher; and as this acid is the starting-point of almost every other chemical salt or body manufactured, these various

salts, *et cetera*, could not be produced nearly so cheaply as at present. As a result of this, the value of all printed and dyed goods would be considerably enhanced, and would be placed out of the reach of many, or at least not easily attained. On the cheapness of this class of articles also, industry in many places depends; so that one may trace much of the trade and prosperity of the country to this beautiful, if not very simple reaction; for though it is possible to produce sulphuric acid without the intervention of nitric acid, none of the methods which have been proposed for the purpose, have gone much further than a laboratory experiment. In a later portion of this article some of these methods will be given.

Having now followed the theory of vitriol-making on an experimental scale, the subject next to be considered is the actual manufacture in the chambers. The construction, *et cetera*, of these, and their various appurtenances, has been already noticed. The chamber arrangement described previously—Fig. 578—has two burners to each chamber; that is, to each of the chambers, A and B. The mode of working these burners is such that a constant stream of gas is sent into the chambers. In order to effect this the burners are charged alternately. Thus, if the two burners attached to a chamber be designated A and B, they are charged at the following hours:—

Burner A.		Burner B.	
Charged at	6 A.M.	Charged at	8 A.M.
"	10 A.M.	"	12 noon.
"	2 P.M.	"	4 P.M.

The same proceedings are gone through with respect to the other two burners. By this mode of charging alternately, it is supposed that as the combustion in one burner loses in intensity the other increases, and *vice versa*; so that a stream of equal volume, or nearly so, is kept up during the whole time.

The burners are charged at the above intervals with a weighed or measured quantity of sulphur. The workman lifts the sliding door, and throws in the charge. Previously to this he inspects the state of the chambers, to enable him to judge what quantity of nitrate of soda he shall decompose simultaneously with the combustion of the sulphur. He puts as much nitre as he thinks necessary into one, two, or more hemispherical iron vessels, or cups, technically termed nitre pots. Immediately he has thrown in the sulphur, he closes the door to prevent the escape of gas; he then proceeds to add to each pot already containing nitre, as much sulphuric acid—from a vessel placed for convenience near the burner—as he considers necessary. This is not a nice or exact operation, the chief point being to add rather an excess of this acid, so as to insure the total decomposition of the salt, leaving a bisulphate of soda, or a mixture of neutral sulphate and bisulphate. When these pots are charged, the door is again opened, and the workman in charge lifts the pots by means of an iron hook, constructed for the purpose, and places them in the burner, in the midst of the now partially ignited sulphur. After a while the sulphur is in a gradually advancing state of thorough combustion, and considerable heat is evolved, which, acting on the nitre pots, causes the complete decomposition of

their contents; the nitric acid is given off, and passes simultaneously with the sulphurous acid into the chamber. A method common on the Continent, but rarely now, if ever, practised here, is the employment of strong liquid nitric acid, contained in basins, and placed inside the chamber at different parts on glass and porcelain triangles. Prefixed to the working chamber is another small one, through which the whole of the sulphurous acid has to pass, while in it are placed a number of earthenware dishes, containing nitric acid. In some instances they are not exactly dishes, but pieces of earthenware apparatus, constructed for the purpose, over which nitric acid is trickled in a slow stream. In either case the object is to expose as large a surface of nitric acid to the action of the sulphurous acid as possible. These two bodies, reacting on each other, produce gases which are carried forward to the working chamber. A rather peculiar arrangement is necessarily employed in order to get the nitric acid into the trays. This consists usually of a number of glass siphons, set into carboys of the nitric acid. These siphons convey the nitric acid into another glass apparatus, of which a bell-jar forms a part; the object of the whole being the conveyance of the nitric acid into the interior of the chamber without allowing any gas to escape. The whole affair is by no means simple, and would scarcely suit the manner of working in this country, as, from its construction, it must be very liable to derangement or destruction. Apart from this, it is not very evident what advantage is to be gained by using the nitric acid arrangement. In the first place, there is all the loss from escape, *et cetera*, incident to the manufacture of nitric acid, as well as the cost for labor, *et cetera*; while, by decomposing the nitrate in the burner, this are economized. Nothing can escape uncondensed, as in making the nitric acid every particle of vapor must pass into the chamber. The combustion of the sulphur affords the necessary heat, while the same labor suffices. On the other hand, it would appear at first sight that by this method the amount of nitrous gas necessary for the chamber could be more nicely regulated; but, on consideration, this advantage appears doubtful, for there would be a difference in the quantity passed through, according as the carboys were full, or otherwise, and the taps could, by a little carelessness of the workman, be left running when there was no occasion for them. Such occurrences have taken place to the destruction of the sides of the chamber.

The only part of the nitre system, if it may be so termed, which appears open to objection, or which may be cavilled at, is the contact of the nitric and sulphurous acids at a high temperature, and in consequence the possible decomposition of the nitric acid either into nitrous oxide or nitrogen, both totally inactive, and for the required purpose wholly useless gases. That such a circumstance has taken place is inferred from a fact which occurred in actual practice. A set of burners were worked to their utmost consumption; they became very hot, and required much more nitrate to keep the chamber in proper working order than previously. It would be difficult, in fact almost impossible, to prove the truth of such an opinion; but, nevertheless, it is

possible, and from the above incident probable; but if, for the sake of argument, the truth of this opinion be admitted, this appears, as far as practice goes, to be the only objection to this method of supplying nitrous gas to the chambers.

A Continental chemist, who employed the nitric acid process, saw the nitre process during a visit to this country, and on his return substituted it for the one he was previously employing; by so doing, he effected a saving of one-third of his nitrate of soda. This result could not have been obtained if there had not been some gross error or carelessness in the mode of working by nitric acid. It is possible that little care was exercised in the manner of working, and that, on employing a fresh process, more attention was directed to the subject; in either case the person was perfectly satisfied with respect to the advantages of working by the English method.

As before stated, however, the heat of the burning sulphur effectually drives off the whole of the nitric acid of the nitrates in the pots, leaving sulphate of soda. The nitric acid as soon as evolved comes in contact with the sulphurous acid from the burning sulphur, and is instantly decomposed by it; often, on looking into the ovens or burners, the whole of the upper portion appears filled with ruddy fumes. These, together with the sulphurous acid, pass up the stalk or chimney which conveys them into the chamber, there to react further upon each other, so as to produce sulphuric acid.

It has been attempted to be shown by the detail of the reactions on a small scale that, theoretically, one portion of nitrous gas is capable of converting sulphurous into sulphuric acid almost indefinitely, were it not that certain practical difficulties intervene; for instance, it must be apparent to the student of these experiments, that although one portion of nitrous gas can go on continually carrying the oxygen of the chamber to the sulphurous acid, yet this action must necessarily stop when the oxygen is exhausted. And this is possible, for were a close chamber taken, containing a limited portion of oxygen with the requisite nitrous gas, and the operator kept on introducing sulphurous acid, it would be found, on testing from time to time, that the quantity of oxygen was slowly diminishing, and that at length it had disappeared altogether.

This could easily have been the case with one of Dr. ROEBUCK'S close chambers, worked on the intermittent system. To supply this, it is usual at the present day to admit such a constant current of air, that there is sufficient to supply a stream of oxygen over and above what is requisite for the combustion of the sulphur; this finds its way into the chamber, there to effect the necessary change. This oxygen becomes gradually appropriated by the sulphurous acid, as the current of gas keeps slowly moving towards the exit with a regular and constant motion; and as this appropriation never ceases, necessarily the gases on passing out must get poorer in oxygen in the ratio of their nearness to the exit pipe. And this is found to be the case, for if a portion of the gases from this spot are collected, and the slight amount of sulphurous acid and nitric gases removed, the quantity of oxygen in the residue will be found to be considerably less than in com-

mon air. The quantity found differs even in the same manufactory, as no rule controlling the quantity of air to be admitted exists. In fact, it is considered advantageous to diminish it as much as possible, so as not to take up the space of the chamber with a useless superabundance of air. But whether this is judicious or not is matter of opinion; however, the reader is requested to bear in mind that, as before shown, the nitrous gas reaches the exit pipe unimpaired, and passes out with the residual nitrogen, excess of air, carbonic acid, and other matters. This is particularly mentioned, as this part of the subject will be again referred to, with respect to the method now in pretty general use for the recovery of this nitrous gas, and its replacement in the chambers, in order again to commence its labor. This invention of GAY-LUSSAC'S is the only improvement of any consequence which has appeared in connection with the manufacture of sulphuric acid for some years; in fact it leaves little to be desired, except the discovery of a material of which to construct the chambers, which, unlike lead, will be indestructible, or at least unacted upon by any of the bodies to the action of which it will be exposed; although, as will be seen in a later portion of this monograph, this problem has been attempted to be solved, its solution has not as yet been successfully accomplished.

Notwithstanding the number of years that sulphuric acid has been, it may be said, a staple manufacture of England, and so much opportunity has existed for studying this process, much misconception as to the true action of chambers exists. The forms, shapes, and other matters in connection with them which have been proposed and built almost exceeds belief—their name is legion; but the prevailing idea, which appears to have actuated many inventors of these ingenious constructions, appears to have been, that the action of condensation in a chamber was simply that of a distillation process; that as the vapor from a boiling liquid in a still or retort condenses on the cold surface of the worm or other refrigerating apparatus, so with a sulphuric acid chamber, the cold walls condensed the acid vapor contained inside. Evidently, with this idea in view, chambers have been built resembling flues; these, having a large surface of cold lead, were supposed to favor the production of the acid by condensing it immediately on its formation. It is related that a clever chemist across the channel constructed a most novel sulphuric acid apparatus. It consisted of an almost fabulous length of lead tube coiled round and round an apartment like a gigantic still worm; that sulphurous acid and nitrous gas were introduced at the highest end; these reacted on each other, the sulphuric acid when formed passing the whole length of the tube, a constant stream issuing from the other end.

It was not stated what length of time this system continued, but certainly on the face of it not long.

It is no uncommon thing to find long lead flues attached to the chamber, for the purpose of carrying off the residual vapors to the chimney. These flues invariably take a most circuitous course, many times longer than the direct route; and as frequently there is no obstacle or other such reason why the flue should not follow the most direct line, one is inclined to

inquire why this latter course was not adopted. If the question were put, the answer would probably be that a steam jet is introduced at the end of this tunnel nearest the chamber from which it issues, and that this length of flue, with the aid of the steam, is expected to condense any vapors not condensed in the chambers. If the product dropping out at the end of this flue be examined, it will very probably be found to be so weak as to be scarcely worth the coals required to concentrate it.

Let the true state of the case be examined. Is it absolutely necessary that there should be a surface for condensation? Is this necessary in all cases, natural and otherwise? Does the rain cloud, which, perhaps, in one half hour will come down in the shape of a heavy shower, require a surface for condensation. If it did, possibly rain would be more manageable; but this watery vapor needs no cold surface; it condenses into water, losing the vaporous and assuming the fluid state, without any assisting cold surface. And if this rain cloud be capable of so condensing, is it not possible for the like physical reaction to take place within a vitriol chamber? But further. Is it not probable, or rather certain, that the sulphuric acid in the chambers never was in the state of vapor. Sulphuric acid requires a heat of 620° to convert it into vapor. The highest point of heat a chamber could attain could be no approach to this; probably the heat of a chamber will not exceed 212° in the hottest part where the gas enters. Is it not possible that every atom of sulphuric acid produced passes from sulphurous acid gas to liquid sulphuric acid at once the instant it is formed—that the chamber is filled with myriads of these newly-formed particles—that these float about, and, like globules of running mercury, they gradually coalesce with each other, until they at last form a particle like a rain drop, sufficiently heavy to resist the sweeping influence of the currents which exist in the chamber; and that, finally, this drop falls into the acid on the floor of the chamber. Although it is impossible to see the process, and so prove the truth of this opinion, a very good inference of its justness may be drawn from an experiment which was tried on a chamber. A strip of lead about three inches wide was attached to the inner side of a chamber, in such a manner that it resembled a gutter or spout in an inclined position, one side of this gutter being formed by the chamber side, the other by the strip. This was placed about from two to three feet above the surface of the acid in the chamber, and was about nine feet long. In consequence of this position, the whole of the acid which formed or condensed on that side of the chamber above the strip would flow along it, and be carried by a small tube passing through the wall of the chamber into a vessel placed on the outside to receive it.

If the liquefaction of the acid took place almost wholly on the side of the vitriol chambers, a pretty rapid current of acid must have flowed along this arrangement, but this was not the case; instead of, as might have been expected, a constant stream passing along it, nothing more than isolated drops issued, probably at the rate of six drops per minute, an utterly insignificant quantity, when compared with the amount

of acid which must have been formed within the space over which this strip had the command.

In fact any observant manufacturer must, after a little attention to the subject, come to the conclusion that such is the case; that condensation goes on chiefly within the space of the chamber, although a small portion may condense on the walls; for when the acid particles are floating about in the chamber—driven hither and thither by the various currents which must exist—some must become attached to the sides and flow down into the acid already at the bottom, adding to the amount already formed. But the argument remains that all the acid is not brought to the liquid state by this means; that, in fact, the quantity thus formed bears a very small relation to the whole.

To many this will be already palpable, but evidently not to all, inasmuch as these strange abortions of chambers are not by any means as yet extinct, but still remain a testimony to the ignorance of many of our manufacturers. It must be apparent, that if anything more than the usual average amount escapes from the chambers, either they are badly worked or overworked. If the first should be the case, more attention must be directed to them to find out the error. If the second suggestion be correct, then, as the chambers have more material introduced into them than they can properly work, the amount of sulphur usually burned must be decreased, until the maximum amount which can be burned with a beneficial result is found. It needs little argument to prove, that the working space included in a tunnel could have been included in the chamber at much less expense.

The introduction of steam into the chambers has been already mentioned. Previously to the use of this reagent, the water on the floor of the chamber had all the work to do; every particle of the sulphuric acid and nitrous compound was compelled to pass in to the water from whatever portion of the chamber it was formed in order to be decomposed. The interior of one of Dr. ROEBUCK'S chambers, or any other chamber worked in the same manner, while in action would have been a pretty sight; the reactions must have taken place consecutively, as described in a preceding portion of this article when treating of the theory of the process. Every particle of sulphuric acid formed must previously have passed through the solid crystalline stage. The interior walls of the chamber must have been each time more or less coated and incrustated with the beautiful snow-like crystals, while the whole interior of the chamber must have resembled a snow-storm in an amber-colored atmosphere. The first manufacturer who introduced steam into his chambers did but exchange a beauty he could not see for a solid reality he could well appreciate. He introduced a most beautiful invention, which not only increased the production in the same chamber-space, but altogether simplified the operation. Instead of, as before, each equivalent of the double compound waiting to fall down into the cold liquid which covered the floor of the chamber in order to be decomposed, leaving, probably, a large per centage of the nitrous constituent behind; the bodies now never assume the solid state but on extraordinary occasions, and then only through

neglect. The whole of the reactions take place in a warm wet atmosphere, where everything is favorable to the intended purpose.

Sulphuric acid, when tolerably concentrated, has a tendency to combine with nitrous acid, forming a definite compound to be treated of hereafter; but unless the acid be concentrated, more so, in fact, than it is usually found in chambers, this compound is very unstable in the cold; heat it and the nitrous constituent flies off.

In a chamber worked on the old plan a great quantity of nitrous gas must have remained in the vitriol, causing a great loss of this body—the most expensive material the manufacturer employs. On the contrary, in the chambers of the present day, each particle of acid as formed must, if sufficient steam be present, be of such a density or strength and temperature as to be incapable of carrying down, and thus removing from its proper sphere of action, any of the nitrous bodies present. Again, in the old plan of working, the nitrous gas was only liberated at the surface of the liquid at the bottom of the chamber. Now, peroxide of nitrogen— NO_2 —the body into which the nitrous gas would become changed the moment after its liberation, coming in contact with the oxygen in the chamber, is a heavy gas, heavier than common air. It can be floated about and poured from vessel to vessel like carbonic acid. This then, on its being set free, would float about on the surface of the liquid, running the risk of being rapidly absorbed; whereas its sphere of action lies amongst the lighter sulphurous acid, on the upper portion of the chamber, to which point this NO_2 could only be conveyed by diffusion, or be carried up by getting entangled with the upward stream of gases emanating from the tube which conducts the sulphurous acid into the chamber. In the present system, whenever a particle of this peroxide or quadroxide of nitrogen meets one of sulphurous acid a reaction commences. Now there is no necessity for a descent to the bottom of the chamber; water, in the shape of vapor, pervades every part of the chamber; and as quickly as the crystalline combination forms, if it does form under these circumstances, it is as quickly decomposed. The resulting sulphuric acid falls, but the nitrous gas forms a second combination, and is then again ready to perform its purpose the moment it comes in contact with another particle of sulphurous acid. When carefully considered, it will be understood that it is not too much to call the introduction of steam into the chamber a great invention. It is not difficult to imagine how slow the process must have been in the old chambers when compared with the rate at which it proceeds now, and what enormous advantages manufacturers at the present day are possessed of over their predecessors.

Much difference of opinion exists as to the proper density at which the acid should be kept in the chamber, or rather what is the maximum density to which it may be allowed to rise? All manufacturers are aware that it is to their interest to keep up the strength of the acid in the chamber to the highest point possible, for by so doing there is a saving of fuel in the concentration. A writer has lately stated, on the authority

of an eminent manufacturer, that it is impossible to keep the vitriol free from nitrous gas if a density of 1.45 or 90 degrees. Twaddell is exceeded; while again in KNAPP's *Technology* it is stated, that the maximum density of 1.585, or about 112° Twaddell, should not be exceeded. A considerable margin exists between the two statements, but in such matters as these, which are not found capable of absolute and precise proof, the only course to be pursued is to take for a guide a near approximation to some recognized authority, or perhaps better, to be guided by the result of practice. A set of chambers now at work are kept at a general strength of from 110° to 112° Twaddell. It is not observed that more than a trace of nitrous gas is absorbed, except occasionally, and these instances may invariably be traced to either a slackening or a total cessation of the current of steam, either from the carelessness of the workman or by accident. In either case the pressure of steam has become so low that little or no watery vapor is being thrown in. Perhaps there is no manufacturer who has not at intervals found his chamber acid so highly charged with nitrous gas as to slightly effervesce when poured with violence from one vessel to another; in fact, it is not an extremely rare occurrence, under some circumstances, to find it perfectly green, from holding a large quantity of peroxide of nitrogen in solution. If, when this takes place, strict inquiry be made, it will be found, that such a state of things results from the chamber having been left for some time, possibly for hours, without steam. This point is worthy the manufacturer's attention, as it largely concerns his profits. The chambers, as at present constructed and worked, are not calculated to work on the old plan. As has been stated before, the steam materially quickens the process, and is the means of much more acid being made in a chamber than could be made were it worked on the old plan. When without steam, the excess which the chamber is not able to convert must pass up the chimney, being a loss of its value as well as risk of nuisance or damage. And not only does this occur, but nearly all the nitrous gas which is dissolved in the vitriol flies off when it becomes hot in the concentrating pan, to no purpose but to annoy the workman and surrounding neighborhood. Such a state of things is not an imaginary case, but a fact, as nearly every vitriol-maker can testify, and that to his material cost.

PAYEN gives a method for economizing this nitrous gas passing from the chamber dissolved in the vitriol. This he proposes to do by passing a stream of sulphurous acid over the surface of the vitriol while being concentrated; the sulphurous acid liberates any nitrous gas or decomposes any nitrous compound, and becoming mixed up and absorbed into this sulphurous stream, is carried into the chamber. The apparatus for effecting this purpose, though ingenious, renders the process of concentration too complicated, in fact, leaving a doubt whether the economy effected by its use is not more than balanced by the inconvenience entailed by its employment. Most manufacturers have a very wholesome fear of what is called a break down, and the general want of stability which this apparatus appears to have is not likely to make it a favorite.

The Recovery of the Nitrous Gas.—The reader will no doubt have borne in mind, that whilst tracing out the reaction of the chamber it was possible to follow the sulphurous acid until it was completely converted into sulphuric acid, and that during this process the whole of the free oxygen of the chamber may become exhausted, but that, nevertheless, the nitrous gas still remains the same. This gas does not enter into, neither does it give up, any essential part of itself to the vitriol; its removal is only on account of its passing off with the current of useless nitrogen and other gases, and when removed it still possesses all its active properties, but diluted and incommenced with a quantity of gas of no value. Many have been the attempts to prevent this loss, and to bring this nitrous gas back into a useable form, and this idea has formed the principal feature in many patented improved methods of manufacturing vitriol. Perhaps the most successful worker in this direction was GAY-LUSSAC, the celebrated French chemist. His process, which was patented in this country, is at present in use in several works, and is found to be perfectly practicable, and to answer well the desired end.

In order that the reader may have a clear general idea of the invention, it is necessary to draw on the imagination a little. Let it be supposed possible to construct a filter through which to pass the unaltered air—nitrogen, trace of sulphurous acid, and nitrous gas—which forms the current constantly passing from a chamber; let this filter have the property of retaining the last-mentioned gas, and of letting all the others pass on to the chimney. When sufficient material has been collected on this filter, let it be possible to remove this retained material and to introduce it into the chamber again, there to renew its former labours, and a view is obtained of GAY-LUSSAC's invention. It has been shown that sulphuric acid, when tolerably strong, possesses the power of absorbing, retaining, or uniting with certain of the lower oxides of nitrogen. Most if not all works on chemistry treat more or less of these combinations, although not much appears to be known about them. GAY-LUSSAC studied them to a considerable extent, and perhaps gave the most just account of them; to this study manufacturers are doubtless indebted for the invention. The formulæ of these compounds are given very differently, arising no doubt from the difficulty of separating the different combinations formed, and then of analyzing them. But they appear to be generally considered as compounds of one, two, or more atoms or equivalents of sulphuric acid and nitrous acid, NO_3 . Some view them as compounds of sulphuric acid and peroxide of nitrogen, NO_4 . But whatever the composition, it is certain that peroxide of nitrogen forced into, or rather passed through strong sulphuric acid, is retained by this acid, and the body in question is formed. This is the principle of the process. It may be performed in miniature as follows:—First, fill a potassa bulb apparatus, or a small Woulfe's bottle with strong sulphuric acid—this is for the absorption—connect this with another Woulfe's bottle containing copper turnings; let a safety or tube funnel be put through a cork in the second neck of this bottle, the other neck being con-

nected by a short length of tube with the absorbing bottle, which also must have two orifices, one of which is to receive a short length of tube leading from the bottle just described to the bottom or lower portion of the sulphuric acid. The second neck must be connected with a suitable aspirator gas-holder. When all is complete, pour a little diluted nitric acid through the funnel on to the copper clippings, having previously set the aspirator at work, drawing a stream of air down the funnel and through the sulphuric acid; after a while, when the action appears to diminish in intensity, pour on a little more nitric acid, still keeping the aspirator at work, drawing the whole current of gases through the sulphuric acid. This must be kept on until the sulphuric acid appears to be becoming saturated; this is indicated by red fumes passing through in quantity. The apparatus may now be disconnected. The rationale, which has been partly described before, is simple. The nitric acid acting upon the copper produces nitric oxide, NO_2 . This, immediately on coming in contact with the oxygen of the current of air which is passing through, becomes converted into peroxide of nitrogen, and this is absorbed by the sulphuric acid, forming a compound with nitrous acid, another with nitric acid, being formed at the same time probably as follows:—

In this experiment the imaginary filtration has been really effected. Excess of air, nitrogen, *et cetera*, have passed on while the nitrous compound has been retained; thus one-half the problem is solved. When the apparatus has been disconnected, empty the bulb apparatus or bottle, as the case may be, into a convenient glass vessel, and pour into a beaker glass a volume of hot water, twice the bulk of the nitrous vitriol; pour this nitrous vitriol slowly into this hot water—a copious evolution of nitrous gas will ensue; in fact, if nearly boiling water be employed, almost all the nitrous gas absorbed will be again given off; a small portion will remain, having formed nitric acid as follows, supposing the liquid to be a compound of sulphuric acid and nitrous acid:—

This NO_2 becomes peroxide of nitrogen in contact with the air. The above reaction has been given before in connection with the chamber reaction, but still it is scarcely out of place.

This experiment then is exactly a representation on an experimental scale of GAY-LUSSAC'S invention. Sulphuric acid forms his filter, by which he separates the valuable nitrous gas from its useless companions, although not exactly in the manner just given. Columns for the condensation of gases are well known pieces of apparatus in all chemical works. They are usually tall hollow towers, constructed, according to the purpose for which they are to be used, of stone or lead. They are filled with pieces or lumps of any suitable material which offers a large surface, and at the same time are not acted upon by the acids or acid gases, or other corrosive substances with which they have to come in contact. Coke offers many points of advantage

in this particular, as it is acted upon in the cold by scarcely any chemical body; and it offers this additional advantage, that while offering more surface than perhaps any other material at all adapted to the purpose, it is at the same time very light. The column to be employed for the absorption of these nitrous gases is filled with coke, and by means of suitable contrivances, to be detailed hereafter, it is kept constantly moistened with a small stream of strong sulphuric acid, which is continually run on to it. The gases from the chambers are made to pass up or through this column or tower on their way to the chimney; and in order to do so, they have to wend their way through the many thousand passages and openings formed by the interstices existing between the pieces of coke. Thus they are split up into numerous streams, and have to come in contact with many hundreds of feet of surface wet with vitriol before they arrive at the exit pipe. The apparatus is built of such size and proportion that the gases in their course upward are brought into contact with sufficient sulphuric acid to absorb the whole of the nitrous gas contained in them. The acid containing the absorbed gas is collected in a proper reservoir or receiver, placed at the bottom of the column for its reception, from thence, as will be seen hereafter, to be removed, in order that it may be decomposed in such a manner that its nitrous constituents may be again used.

This apparatus seldom or never works well when applied on the small scale, as, for instance, when applied to one or two small chambers. This is a practical difficulty which, perhaps, in the hands of a careful and determined person, might be got over. It has been applied on a small scale at several works, and has been given up. On the other hand, several vitriol manufacturers on a large scale who use it, speak very satisfactorily of its performance. In some cases, by its employment, the consumption of nitrate of soda has been reduced from one-tenth the weight of the sulphur employed to one-twentieth—in fact, to the extent of one-half of that previously used. This is certainly a very good result.

The dimensions here given are those of an apparatus which is applied to a set of chambers, in which an average of eighteen tons of sulphur are consumed or converted into sulphuric acid per week of seven days. The apparatus is seen in Fig. 582. It consists essentially of the column or tower itself, three cisterns for holding or containing vitriol—*a*, *b*, and *c*—together with a large close cast-iron cylinder, *d*, employed in raising the vitriol to be used for absorption from the surface to the upper cistern at the top of the column, and also for removing this when nitrated or saturated with nitrous gas. The tower cannot be more appropriately described than as a tall cylinder of lead, five feet diameter, and thirty feet high, supported, like the lead of the chamber, by a suitable strong wooden framework. This leaden cylinder is completely closed in at the top, and stands in a suitable leaden dish or tray at the bottom, of such a depth that it always contains vitriol enough to lute it, and so prevent any escape of gas. The thickness of the lead is from a quarter to half an inch—some manufacturers preferring to use the thinner variety from motives of economy, while others, in order

to insure absolute safety, prefer to use half-inch lead. This cylinder, as stated before, and as shown in the drawing, is filled almost completely with large pieces

of coke. The quality of this coke is not by any means a matter of indifference: it must be in large firm pieces, for if it is either in small pieces of a rotten or soft

Fig. 582.

variety, it must be rejected; for, if small, sufficient space will not be left between the pieces for the proper passage of the gas, but will choke up the whole apparatus: besides the weight of the coke in the upper portion of the column will crush that near the bottom, and a similar result will follow. It will be, perhaps, well to mention, that if quarter-inch lead is used in the construction of the column, it would be well to line it with thin fire-tiles. These must be applied simultaneously with the filling in of the coke, as it would be impossible to hold them in their places otherwise; they must be placed as close as possible to the lead, and pressed to it, and held in their places by the coke pressing against them. This precaution of brick lining is necessary to prevent—what might otherwise occur—the cutting of the lead by the sharp edges of the coke; for although the column may be quite full at the first, yet, after a while, it will be seen that the whole mass

has subsided some inches, has in fact settled down, and were the tiles not in their places to protect it, it is possible that a sharp edge of coke might cut a slit in the lead.

It is necessary to have some arrangement at the bottom of the column by which the gases from the chamber can have unobstructed entrance, for were the coke at once thrown in, without some contrivance for this purpose, it would fill up the entrance pipe, and prevent or nearly so, the entrance of the gases. A very good arrangement for this purpose may be made with fire bricks, which are almost unacted upon by acids. The lower part of the tower or column, to a few inches above the entrance for the gases, is filled in with these fire bricks—arranged in a systematic manner; in fact, built up in the most open and loose manner possible, so as to allow the greatest amount of inlet to the gases. The coke is piled above this. By this arrange-

ment the gases have all but a totally uninterrupted entrance; they rush up through the wide spaces left by the brick, and from thence divide themselves amongst the numerous passages which they find between the coke.

At the top of the column is placed the cistern containing the vitriol, which is run down it. Care should be taken, in the construction of an apparatus of this kind, that the timber work is sufficiently strong to bear the rather heavy weight of this cistern; but this, of course, is what few would overlook. Inserted into what may be called the roof of the column is a device for spreading the vitriol over the whole surface of the coke. In fact a good deal depends upon this, for were the vitriol run on just in one spot, it might possibly find its way down in one small stream not capable of taking up the nitrous gas, in consequence of its having little surface. KNAPP recommends this spreading to be effected by a series of cones placed within each other; these cones, which, as might be supposed, are constructed of lead, have each the apex removed, and the open ends of the whole system are placed immediately under an orifice in the roof of the column. The vitriol is made to enter these open ends in flushes; it rushes over the surface of the different cones, and finds its way to the interior, wetting the coke with a series of concentric circles of sulphuric rain. This will be understood by referring to Fig. 581.

A method which answers tolerably well is shown in Fig. 583. This is an arrangement actually in use. It will be better understood by supposing a broad flat dish, about two-thirds the diameter of the column

Fig. 583.

itself, to be placed on the roof of the column. Into this are inserted a number of tubes—about twenty or thereabouts; these tubes protrude both down into the column, and for a shorter distance up into the dish. The under portion of the tube can be bent, so that the stream which it delivers can be directed to any point desired; for instance, let the whole area of the column be mapped out, and twenty different equi-distant spots be marked; a tube is directed over each of these spots, so that when in action the coke is wetted in twenty different places, in this way increasing the chances of the whole body of it getting thoroughly moistened. Whatever mode of attaining this end may be adopted, the use of an oscillating box, or what the workmen, perhaps more expressively than elegantly, term a *tumbling box*, is almost absolutely requisite; for, in the

last-described scheme, without such an adjunct the spreading would be very inefficiently performed. The stream of vitriol which is run down a column of this description is, comparatively speaking, very small; and when this comes to be divided into twenty separate streams, they must naturally become very much less; so much so, in fact, that the chances are, that unless the ends of the tubes which project into the basin are exactly of one level, which practically is impossible, some three or four which happen to be the shortest, will take almost the whole of the stream. This casualty is put out of the question by the use of the oscillating box, the action of which is to deliver a comparatively large body of fluid at intervals, and this from a small stream. It is easy to see that each time the box oscillates and delivers, say a quart of fluid, the height of the liquid in the basin suddenly rises, and then immediately subsides, enough fluid having been delivered to furnish a current for each of the twenty different tubes.

It would, perhaps, be well here to describe the construction of one of these oscillating boxes, notwithstanding their being well known, and their action thoroughly understood. It is an old invention, and has been figured and described in many works on chemistry. It is constructed of a shape similar to that of two cones fastened together at the base and sectioned, with an axis connecting the apices; this will be seen by referring to Fig. 584. This apparatus, as depicted, is a diamond-shaped box, open at the two upper, and closed at the two lower sides. The box is divided into two by a partition, *a*, in the centre, and the whole is mounted on an axis, *b*, on which it can oscillate. It works, in this manner, one of the two spaces caused by the division, presents itself to the tap of the cistern, or other vessel, whence a small stream is issuing. It will be seen, by examining the figure, that the fuller one of these spaces becomes, the more to that side must the centre of gravity incline, until at length this centre of gravity gets thrown so far beyond the axis, as to overbalance the empty side of the box. When this occurs, the whole of the liquid which this division contained is emptied out suddenly, and the other side presents itself for filling; the apparatus taking the position indicated by the dotted lines. Of course, in a short time, this side becomes full, when a reverse again occurs, and so on as long as there is sufficient liquid to keep it in motion.

Fig. 584.

Another point of some importance in connection with the economizing powers of this column, is the regularity of the stream of acid which runs down. If the tap of the cistern, whence the acid flows, is set to a certain speed at the commencement of the space of time during which the acid is to last, it is certain that it will not run at the same velocity when the cistern is getting nearly empty; nor, according to the proper physical law which controls these matters, will it run with the same force during any two portions of time. According to the law, the rate decreases as the square root of the depth; or, to take a practical and easily understood illustration—suppose it is a cistern three feet deep, then whatever the

number of quarts, gallons, or other volumes per minute at which it runs, it will be delivering exactly half that number when the cistern has lowered to nine inches deep. Thus at one time there would be running down exactly half the quantity as at another; at one period probably supplying the apparatus with more vitriol than is necessary to take up the nitrous vapors, and at another time not giving it sufficient acid, thus allowing a valuable substance to escape.

This idea appears to have struck either the original inventor, or an early employer of this process; for in KNAPP'S *Technology*—which appears to be the only book in which a description of this process is inserted—a drawing of a method of obviating the defect is given. It is there proposed to employ a closed cistern, in principle resembling a bird's drinking fountain, where water can only be obtained by replacing the space occupied by it with air; and to cover this cistern with a top constructed of thick lead, supported in the interior by iron rods, sheathed in lead, to protect them from the action of the acid. When working, this apparatus must have had two alternate currents passing through the tap, one current of air into the receiver, to supply the place of the acid flowing out of it into the oscillator.

Several objections to this plan present themselves. In the first place, such a closed cistern must have been very inconvenient to work, in consequence of the increased amount of manipulation; for it was necessary to have an orifice in the cover through which to fill it. This aperture required to be made perfectly air-tight when the cistern was filled; for if this was not done, the whole principle involved became nugatory. Again, the construction of such a receiver must have presented many difficulties, not to speak of the great liability to leakage in the cover and other parts of the cistern. Besides, when the cistern leaked, a great portion of the cover would require to be removed, in order to admit a workman to repair it; the cover itself would also have to be repaired, taking up much time, during which the whole apparatus would be inoperative.

Many other objections present themselves on examination, but are scarcely worthy of remark, inasmuch as no cistern of this construction appears to be at work at this time, at least in this country.

An apparatus which answers the desired end very

well has been applied; and it has none of the objectionable features just described; it is shown in section in Fig. 585, where *a* represents the cistern containing the supply of acid. Adjoining this cistern is a circular vessel of lead, twelve inches in diameter, and of the same height as the cistern. Between these two, and from the bottom of each pro-

ceeds a tube, *b*, which forms a passage between them. This tube is not a whole piece of tube, neither does it take the shortest course between the two vessels, and

this for a reason which will be presently shown. The upper portion of the pipe opening into the cistern is of a conical shape, and into this is fitted a conical lead plug, which has been cast on a long iron rod, and turned up in a lathe very smoothly and with great nicety, so as to fit very accurately into its seat, the conical mouth of the tube just mentioned. This plug, as shown in the drawing, has the iron rod, which forms its stem, prolonged below the plug proper some eight or ten inches. This portion, as well as the upper, up to within an inch or two of the hook at the top, is coated with lead. This coating must be done very accurately, to insure the exclusion of the acid from the iron rod. This is best done by pushing the rod through a lead tube of the proper diameter, and fusing the extremities of the upper and lower portion to the plug proper by means of the blowpipe jet, described in that portion of this article which treats of the construction of the chambers. The lower length of the rod moves in the straight portion of the tube below the cistern, and is for the purpose of preventing the plug getting out of its seat, as well as for accurately guiding it in.

Within the tall cylinder before spoken of hangs a leaden bucket, for so it may be most appropriately called; the rim, or upper edge of this bucket, has an iron ring inserted into it, for the purpose of keeping it in its proper shape. To this ring are attached three iron chains, not unlike, in thickness and general appearance, to dog-chains. These chains are attached at a short distance to a single chain, which hangs in the centre of the cylinder. The upper end of this chain is in its turn attached to one end of a lever, moving freely on its axis, situated at the middle of its length. To the other end of the lever is attached another short length of chain, connecting the end of the lever with the hook at the extremity of the plug. This lever has semicircular pieces of iron attached to its ends, over or on which the chains rest, in such a manner that the plug and bucket have each, as near as may be, a true vertical motion, so that the plug may descend exactly into its seat, and that the bucket may move up and down precisely in the centre of the cylindrical vessel. This cylindrical vessel has the delivery tube fastened to it, and the tap from which the stream flows attached to it again.

In order to work effectually, imagine that the apparatus is newly attached, and has not been used before, and that this is the first trial. Let one imagine that the plug has been inserted unattached to anything else into its seat, and also that the cistern is full of vitriol; also determine that the vitriol shall run out at a pressure of some six or eight inches—vitriol pressure, not water. To do this, let the bucket hang down in the cylinder some six or eight inches from the bottom; attach the chain to the lever, and then attach the plug by means of the chain to its other end. In both cases this should be done so that the lever remains in a horizontal position; then let the bucket fall to the bottom. The result of this will be that the plug will be drawn from its seat, and the vitriol will run from the cistern into the cylindrical vessel through the communicating pipe. Now, watch

Fig. 585.

the action of the apparatus as the vitriol rises in the cylinder. As it does so the bucket will rise. Now, as first said, this bucket is fastened to one end of the lever, while the plug is fastened to the other—in point of weight the plug is the heaviest. Under these circumstances it naturally follows, that as the bucket *ascends* the plug descends, until at last the bucket ascends so high that the plug falls into its seat, and effectually closes the passage. If allowed to remain, and if the plug fits well, the liquid rises no higher in the cylindrical vessel. But if the delivery tap be opened the liquid in the cylinder will be seen to subside, the bucket descend, and the plug be lifted from its seat so high that it allows just so much liquid to pass it as is running out through the tap, whatever this quantity may be.

Thus, on examining the action of this apparatus, it will be found that it allows the cistern to be run almost empty at precisely one pressure, either six, eight, or any number of inches, thus obviating the misjudgment of the workman, or, what is probably oftener the case, the total neglect of its rate of running. A careful workman, from constant practice, soon learns to set the tap so that it shall run many hours without altering; he has only to notice the time required to run so many inches out of the cistern, it having a gauge with inches marked on it for this purpose; from this he can easily calculate, from the depth of the cistern, whether it will last out the required length of time. If the rate of running is not correct, it must be altered less or more accordingly. As this apparatus is not patented, it may probably find other applications.

Having now described the mode of running the acid down the column, let attention be turned to another and previous portion of the subject—the manner of placing it in the cistern. It is well known, and is a matter of no little regret, that as yet there is no real acid pump. Weak vitriol can be pumped with a pump of the ordinary description—the barrel formed of lead, the valves and all the flexible portions being formed of caoutchouc. But this latter body, and every other body which serves its purpose for ordinary liquids, is destroyed in a few hours, when placed in strong sulphuric acid even when cold. Such being the case, another contrivance is adopted—a very useful although not a very new one, it being at least as old as the chemist's eductorator, used in analysis for washing precipitates. This apparatus, as is well known, enables one to drive out a rather forcible though small current of water by atmospheric pressure applied on the surface of the water contained in the bottle. This is effected by closing the neck of the flask or bottle employed with a cork through which two tubes pass, one of which descends to the bottom of the flask below the surface of the contained water, while the other merely protrudes below the bottom surface of the cork. By means of the mouth, air is forcibly compressed within the bottle; this, in its efforts to escape, drives the water before it in a stream; and this is the principle of the apparatus by which the vitriol is elevated. A large cast-iron vessel, *e*—Fig. 582—replaces or rather represents the washing bottle. This vessel is for con-

venience placed in a walled cell or space dug in the ground, and is made of such dimensions that it will hold rather more than the cistern it is destined to fill. It is formed not unlike a soda water bottle, this shape being the strongest, the lower and upper ends being rounded, the latter having a flanged neck cast upon it; this being about one foot wide. This flange has a number of bolt holes cast in it, corresponding to a like number of bolt holes in the lid. The lid has two perforations cast in it through which two two-inch diameter pipes can be passed and be secured, one of which pipes, as in the case of the wash-bottles, passes to the bottom, or nearly so, leaving a space of merely two or three inches; the other pipe merely passes through, terminating beneath the lid. Perhaps the best method of making a secure joint between this lid and the vessel flange is to insert an India rubber ring of such a size that it will lie within the circle of bolts; the ring being thus placed, the bolts are put in and screwed up tightly, thus compressing the elastic washer, and forcing it to fill up every crevice, so as to be effectually air-tight. The whole of this description will appear much clearer on referring to the figure—Fig. 582.

The drawing which accompanies this is scarcely complete, inasmuch as one cistern has been left out; this has been done purposely, so as not needlessly to complicate the figure. In order to explain the drawing the reader must consider himself working the apparatus. In the first place, suppose the iron cistern, *e*—Fig. 582—to be filled with vitriol of the density 1.750, or 150° Twaddell, this being the strength of vitriol to be used in the absorption of nitrous gas. At this moment it does not matter how it was filled. By means of a powerful air-pump, a strong pressure of air is forced on to the surface of this vitriol, driving or forcing it up the pipe, *f*, into the cistern, *a*, which it fills. From this cistern it runs, as has been already described, into the column, where, after traversing the coke with which it is filled, it runs into the dish-like vessel in which the column may be said to stand. From this it runs by means of the pipe, *g*, into the cistern, *b*; it is now by this time saturated, or nearly so, with nitrous gas, which it has gathered during its passage down the tower. From this cistern, *b*, it is once more run into the iron underground vessel; the air-pump is once more put into requisition, and it is forced from this vessel into the cistern, *c*, there to be reserved and run off as wanted, to be decomposed in the chamber.

As before stated, the cistern for the raw vitriol is not included in the drawing, but, as it is only a copy of the one at the foot of the column which is represented, a description of the one will serve for the other; it will also suffice to describe how the nitrous vitriol is conveyed from the cistern, *b*, into the cistern, *c*. It will be seen that from the bottom of the cistern, *b*, a short tube proceeds, which immediately joins on to the main pipe or artery, *f*; into the conical mouth of this pipe which opens into the cistern, a plug is fixed, which plug, like the one already described, is simply a conical boss or mass of lead cast on to the end of a sufficiently long rod of iron, and turned in a lathe to a fine surface, so as to make as accurate a fit as possible, the shank being sheathed in lead so as to

preserve it. The upper end of this rod is split, so as to embrace a lever, to which it is firmly attached by a hinge-like joint. This will be better understood by referring to Fig. 586, where *a* is the plug, as already described; *b* is the lever to which it is attached; *c* is a joint at one end of the lever, and which serves as a fulcrum; *d* is the handle at the other end of the lever; *e* is a guide in which it works, and which confines its movements to a simple vertical motion. The plug apparatus is fixed, as shown in Fig. 586, across the corner of the cistern. Now, to get the vitriol in *b*—Fig. 582—into the iron vessel, the workman simply

Fig. 586.

lifts the plug at the corner of the cistern; this he does by a sudden jerk, after loosening a little piece of apparatus, to be hereafter described, and which is for the purpose of keeping the plug in its place and preventing its rising when the pressure comes on to its under surface. Immediately he lifts this plug the sulphuric acid proceeds to run down this short tube into the main artery, and thence into the cylinder, driving out the air through a tap placed for the purpose. Immediately the cistern is empty, the workman by a forcible thrust fixes the plug in its seat, and for fear the pressure should force it out, he proceeds to fasten it down, as shown at the cistern, *b*—in Fig. 582—where in the upright, *h*, a number of holes are shown; into one of these a cotter, or piece of round rod iron, is thrust; then between this cotter and the lever he drives in the wedge, *i*, thus effectually preventing the rise of the lever, and consequently firmly holding the plug in its place. As soon as this is accomplished, he proceeds to set the air-pump in action, which air-pump injects air on to the surface of the vitriol; and when sufficient pressure has accumulated, the acid gradually flows along the horizontal pipe and main artery, *f*, until it arrives at the pipe, *f*, along which it proceeds, eventually emptying itself into the cistern, *c*, the air-pump being kept in action until all the vitriol is forced out of the cylinder, and a small portion of air following indicates when this has taken place.

The next part of the process is the conveyance of raw vitriol into the cistern, *c*. The details are precisely similar to those already described. Let the reader imagine another cistern precisely like cistern *b*, a perfect copy plug included, which said cistern has a short plug connecting it with the main pipe or artery, *f*. As in the case of cistern *b*, the workman removes the plug, and allows the vitriol to flow into the iron cylinder as before; when he has done this he proceeds to take measures for projecting this charge into the cistern, *a*, at the top of the column.

On the branch pipe leading to the nitrous vitriol reserve cistern, *c*, a plug apparatus will be observed. This is for the purpose of closing this branch pipe while raising the raw vitriol, and is taken out when the nitrous vitriol is being pumped up. It is scarcely necessary to remark that when the nitrous vitriol flows through this branch pipe, it naturally issues at the open end over the cistern, *c*, such being the lowest. In order to prevent

the raw vitriol taking the same course, the workman firmly inserts and fastens down this plug, and, when the acid to be used for absorption has filled the iron vessel, he sets the air-pump in motion, and the vitriol rises up to and flows into cistern *a*.

In consequence of the height of the column of liquid rising from the bottom of the iron vessel to the upper edge of the cistern, *a*—a space of nearly thirty-eight feet—and of its superior gravity, a pressure is exerted approaching to thirty pounds on the square inch. Hence it will be apparent that the cylinder and its appendages must possess a considerable amount of strength. It is usual to have them cast two inches thick in the sides in order to withstand this weight.

The air-pump used in this case, and which has been so often mentioned, is constructed on the model of an iron furnace-blowing engine, and differs from it only in dimension. The cylinder of this pump may be about eight inches diameter, the length of stroke being twelve inches, and it makes about fifty strokes per minute. It has a rather heavy fly wheel attached to it, to steady its action. This is necessary on account of the great resistance it has to overcome at the end of each stroke. It is necessary that the piston should fit very accurately, and that about the pump and the fittings generally great care should be taken to insure perfect freedom from leakage.

The quantity of sulphuric acid used in the absorption is rather variable, some manufacturers being more successful in this respect than others. Many who employ this apparatus recommend one-third of the make to be run down every twenty-four hours. In this case, for every hundred tons of acid made per week, nearly five tons would be run down per diem. One manufacturer finds in practice that about four hundred gallons, or seven thousand pounds, run down the column every twelve hours, will absorb the nitrous gas from a set of chambers which are converting eighteen tons of sulphur weekly into sulphuric acid.

To utilize the nitrous vitriol it is necessary to liberate the nitrous acid it holds, either within the chamber or contiguous to it, and in presence of the sulphurous and other gases entering it. Simple dilution with water effects this, as explained at page 1033. Still its practical working at first was found somewhat difficult, and much ingenuity has been expended in improving this part of the process, but still something further remains to be done before it can be considered perfect. The original inventor gave a method which, though theoretically almost perfect, was, unfortunately, not quite so, practically. It consisted in exposing the nitrous sulphuric acid in thin films or sheets to the action of the sulphurous acid which issued from the sulphur ovens. By this he proposed to liberate the nitrous gas, and in part he did so. The apparatus is shown in Fig. 587, which represents a sort of leaden column. Within this column a series of horizontal shelves or partitions are placed, which almost fill up the whole of the area; a funnel, furnished with an S tube, is inserted into the roof, and through this the nitrous sulphuric acid is poured on to the shelf immediately beneath. It runs from this first shelf on to the next one, and so it proceeds to the bottom, in exactly an opposite direction to that

pursued by the sulphurous acid current, fresh portions of which it meets at every point of its progress downwards. The funnel tube is of an S form, for the purpose

Fig. 587.

of preventing any of the gas escaping, a quantity of the liquid being retained in the curvature of the tube sufficient to prevent effectually the loss of any gas.

The sulphurous acid is admitted into this column through the wide tube at *a*, while immediately above this a jet of steam is thrown in; these together, after traversing the spaces between the shelves and acting on the downward stream, finally escape laden with nitrous gas into the chamber through the passage, *b*.

The jet of steam just mentioned is for the purpose of diluting the nitrous sulphuric acid, and so causing it to yield up more readily the nitrous gas.

The acid, by the time it reaches the bottom, is supposed to be thoroughly denitrated, and is conducted thence to an evaporating pan to be concentrated, in order that it may be once more used for the absorption of a fresh portion of gas in the absorbing column. Theoretically considered, the nitrous vitriol ought to run from the lower portion of the apparatus without containing more than a trace of any nitrous body. On the contrary, it might be expected to be charged with sulphurous acid, but practically this does not appear to have been the case; for, from the statement of those who had ample opportunity of examining its action, it appears that the nitrous constituent was never thoroughly eliminated, that it still retained a considerable quantity of this gas after very slowly traversing the apparatus, and that this impossibility of thoroughly decomposing the compound acted as a strong barrier to the introduction of the invention. But, happily, this defect was not unconquerable, and was, by a reasonable amount of skill and patience, eventually obviated, at least practically so, if not perfectly.

The nitrous sulphuric acid is decomposed, but comparatively slowly, when subjected to the action of sulphurous acid in an undiluted state; and this appears to have been the cause of the failure in the commencement, inasmuch as the acid flowed from the decomposer almost of the same density as when introduced. It would seem inconsistent that the expedient of mixing it with water so as to dilute it was not adopted, especially as the decomposing action of water *per se* must have been observed. Doubtless this would have solved the problem, especially as with this addition a modification of his apparatus answers very well.

The mere dilution of this nitrous sulphuric acid with hot water answers very well. This is done within the chamber. A section of the apparatus employed is shown in Fig. 588. It consists in simply placing within

the chamber, and as near the burner stalk as possible, a round leaden vessel about twelve inches high and eighteen inches diameter. This is placed close to the

Fig. 588.

leaden wall of the chamber. This leaden wall is pierced by three tubes, all terminating within the leaden vessel, and near to its bottom. One of these tubes conveys the nitrous sulphuric acid into the vessel; the second conveys water; and the third is a steam-pipe. The two tubes for the liquids terminate on the outside of the chamber in funnels, while above these funnels are the respective taps, one of which communicates with the nitrous vitriol-store cistern, and the other with the supply of water. The steam-pipe is, of course, in connection with a generator.

Supposing the chamber to be at work, the mode of operating, with this arrangement, is very simple. The leaden box or vessel is first run full of water—this is by means of the steam jet brought to boiling. The operator or workman then proceeds to run in a slow stream of nitrous vitriol and water from their respective taps. Immediately the nitrous vitriol touches the hot water below, it decomposes into sulphuric acid simply,—which remains in the vessel for a while—and nitrous gas, which flies off, and which is, by the current of gas ascending from the burner, carried off, and enters into the working of the chamber.

Of course, the vessel always remains as near as possible full. The streams of fresh liquid running in immediately displace and drive out a portion of the previous contents, causing it to mix with that already contained in the chamber.

There are at least two advantages which arise from placing this decomposer as near the burner-pipe or gas tubes as possible. In the first place, the gas arising from the decomposition has a better chance of thoroughly mixing with the rest of the gases which form the chamber mixture; and, in the next place, this rapid removal and immediate mixture lessens the risk of local action on the chamber, nitrous gas being rather destructive to lead. In fact, the rapid current of sulphurous acid gas must sweep away every particle of nitrous gas as fast as it is liberated. One of these decomposers has been working in a chamber for nearly three years, and the lead in its immediate neighborhood does not appear to have suffered more than that in any other part of the chamber.

Mr. PETER HART of Manchester has given a method of estimating the value of this nitrous vitriol

by a process of analysis by which one may, in a very simple manner, determine how much nitrate of soda or nitric acid a given volume of this nitrous vitriol represents, or is equal to. The process is founded on the well known reaction which takes place on bringing nitrous acid and urea together, the result of this proceeding being the formation of water, nitrogen, and carbonic acid gases, as shown in the following formulæ—

Mr. HART prefers to employ urea, in the shape of nitrate, on account of the facility with which it can be obtained pure. Of this nitrate of urea he weighs out twenty grains, and dissolves this in about two and a half ounces of water, heating this solution to boiling over a gas lamp. Meanwhile he prepares a test liquid, composed of thin starch water, in which he dissolves a small quantity of iodide of potassium. He spots a white plate with drops of this liquid. He then fills up an ordinary alkalimeter with the nitrous vitriol to be tested. Meanwhile the solution of urea has arrived at boiling, at which point he lowers the gas flame, and proceeds to add the nitrous vitriol from the alkalimeter to the solution in the basin. The reaction goes forward with strong effervescence, and escape of nitrogen and carbonic acid gases. He continues to add the nitrous vitriol drop by drop, not neglecting to stir until a drop, taken out of the basin by means of a glass rod, and added to one of the test spots on the plate, causes the latter to assume a blue color. This indicates the completion of the operation. The number of measures used or added are read off, and this forms the data for the calculation. The rationale of the process is very simple. After the decomposition of all the urea, the nitrous acid, which hitherto has been simultaneously decomposed with the urea, now remains in a free state. Now, it is well known that nitrous acid decomposes hydriodic acid, setting iodine free, which iodine will immediately combine with starch, if any be present. This is one of the tests for nitrous acid; so in this case the formation of the blue coloration indicates free nitrous acid in the basin; and free nitrous acid present indicates the decomposition of all the urea.

The calculation is based on the fact, that to decompose the twenty grains of nitrate of urea employed, there would be required 12·35 grains nitrous acid, NO_3 , which is equivalent to, or represents in chamber effect, 17·56 grains nitric acid, NO_5 , or 27·64 grains nitrate of soda; consequently the number of alkalimeter measures of the nitrous vitriol required in the decomposition represents or contains the equivalent of any of these numbers. All that remains to be done is, to ascertain the relation borne by this quantity to the volume which the cistern is capable of holding, or contains at the time of the experiment; or to put it as Mr. HART gives it—let a represent the number of alkalimeter measures employed of the nitrous vitriol; b the nitrate of soda—if the result is required in nitrate of soda—corresponding to the twenty grains of nitrate of urea, as given above; c the number of alkalimeter measures in a gallon—

seven thousand—and d the number of gallons in the cistern; then—

$$\frac{b \times c}{a} \times d = x$$

x indicating the equivalent in nitrate of soda of the recovered nitrous acid in the entire cistern.

Another method of recovering the nitrous gas has been lately patented in this country. It differs very considerably from the one already described, that is, in principle, although the apparatus bears a great resemblance. It consists essentially in converting the nitrous gases into nitric acid, and combining this acid with lime. The inventor starts out with a column, as in the last process, filled with suitable materials to afford a large surface, down which he runs a stream of thin milk of lime, allowing the waste gases from the chamber to ascend in the opposite direction. In this case it is supposed that, under the influence of the alkaline fluid and excess of atmospheric oxygen, the oxides of nitrogen will be wholly converted into nitric acid, which will immediately combine with the lime, forming nitrate of lime.

It is well known that nitric acid can be reproduced from any of the lower oxides of nitrogen—with the exception of, perhaps, the lowest, nitrous oxide, NO , when in contact with water and free oxygen. This has been dilated upon, and the reaction given when treating of the chamber reaction; and that this is a fact there is no doubt. The only difficulty hitherto appears to have been to obtain nitric acid of a suitable strength. This has scarcely been accomplished, as experiments have shown that the reaction proceeds with less rapidity as the acid gains density. But where lime-water is used this objection is removed, inasmuch as no free acid can exist in the liquid to retard the reaction; each atom of this acid being removed or combined at the moment of its formation, or immediately afterwards. There is no doubt that the presence of an alkali not only obviates this retardation, but actually induces, by its presence, the combination of the lower oxides of nitrogen with oxygen, thus, in fact, acting in a doubly advantageous manner.

The solution of nitrate of lime, formed in the column, is run into a proper cistern placed for its reception and conservation prior to its being converted into a dry or crystalline salt, which the inventor proposes to employ instead of nitrate of soda, as a constituent of the artificial manures now so much in request.

Perhaps the process would have been more perfect had it been more self-containing, and not dependent on outer circumstances for its perfect well-doing; that is, if the vitriol manufacturer, instead of having to depend on the purchase of this nitrate by other parties, could have used it himself. Were it cheaply decomposable, that is to say, were it possible to eliminate the nitric acid cheaply, it would be better; but it can only be decomposed with ease by the addition of some stronger acid, and the only one reasonably available for this purpose is sulphuric acid. By substituting this nitrate of lime for the nitrate of soda or potassa, ordinarily employed, one would certainly most effectually get back the nitric acid; but, unfortunately, sulphate of lime, a body of no value, would be pro-

duced, instead of, as now, producing sulphate of soda or potassa, salts in great and constant demand.

Of the value of processes for the recovery of the nitrous gas little need be said. The benefits they confer are apparent at once, recovering, as they do, the most expensive element in the manufacture, and not only being a saving of the money value of the nitre or its equivalent recovered, but further, when looked at in a politico-economical point of view, another phase presents itself: for were all sulphuric acid manufacturers able to work with half the nitrate they at present use, it would surely tend to reduce the price of this salt; and, if the maxim be correct, that price is regulated by supply and demand, then under the imaginary state of things just mentioned, one-half the quantity now used being thrown on the market, or what is the same thing, not used, must bring down the price of what could be sold, thus lowering a second time the cost of manufacturing sulphuric acid.

Concentration of Sulphuric Acid.—Sulphuric acid, as it exists in the chambers, though strong enough for many purposes, is not sufficiently so for sale, inasmuch as it is the object of the manufacturer to send it out as strong as conveniently may be, in order to avoid the necessity of conveying a quantity of useless water. It is concentrated up to a certain point in leaden pans; that is, until it has attained the density of 1.750; beyond this point it is not considered safe to push the concentration in lead. In order to bring it up to its maximum degree of concentration, or its conversion into what is termed rectified oil of vitriol, the extrication of the further remaining quantity of water must be performed in vessels of glass or platinum.

With respect to its concentration in lead a variety of plans are in use for this purpose. Much difference of opinion exists on this head amongst sulphuric acid manufacturers; their choice probably depending on convenience and situation. One manufacturer, for instance, prefers to concentrate his vitriol by passing the flame and products of combustion of a fire over the surface of his weak acid, the watery vapor being carried away with the smoke, *et cetera*. This plan appears to answer very well where no niceness with respect to the color and purity of the acid is demanded—as when the vitriol manufacturer is also a soda manufacturer, and uses up his own acid; but as the concentrated acid resulting from this mode of working is almost invariably very black and turbid in consequence of particles of coal-dust, *et cetera*, falling into the hot liquid, as well as from contact with the various carbonaceous bodies forming coal smoke, such acid would be scarcely saleable in the ordinary way to calico-printers, bleachers, and other such consumers. In order to avoid this, the manufacturer must employ an apparatus in which the liquid is kept clear from all or any such contaminations. For this purpose a pan in principle, though not in shape, resembling an ordinary pan or boiler, must be employed. This variety of concentrating boiler is in very general use, being, in fact, almost universal amongst those manufacturers who sell their acid; whilst the surface concentrator is as commonly employed amongst the soda manufacturers and others, who make the acid solely for their own use,

The following describes the plan of a manufacturer who makes for sale only. This plan is found to answer very well; it consists of two pans, placed side by side, one being placed higher than the other—so high that its contents can be emptied completely by means of a siphon into the lower pan. No joinings or solderings of any kind are admissible about these pans, the whole must be formed out of one solid sheet of lead,

Fig. 589.

the sides and ends being turned up simply: the lead is half an inch thick, the other dimensions of the sheet being thirty-three feet by seven feet six inches. To form such a pan, the sheet of lead is first spread out on the bed prepared to receive it; the plumber proceeds to mark off eighteen inches from each side of the sheet; this is to form the sides and ends of the pan. To faci-

litate the bending, a fire of shavings is made along the line of markings. When the lead has become sufficiently hot along these lines, he proceeds to bend up the sides, and to beat out any inequalities. The brick-work setting of the pans will be understood from the preceding figures, in which Fig. 589 represents the arrangement of the flues, previous to being covered in with the fire-tiles or iron plates on which the bottom of the pan is to be placed; the left hand portion represents the bed of the lower pan, while to the right we have that of the upper one. *a a* are the two fire-places, the flame from which proceeds along the narrow flues or passages, *b b b b*; they turn off at the end in the direction of the arrows, and return beneath the upper pan, along the two wide flues, *c c*, and from thence pass into the wide flue leading to the chimney. Fig. 589 is a vertical section, lengthways, of the fireplace of the lower pan; *c* is the course of thick fire-tiles immediately over the fire, protecting the pan from the too great heat; a little beyond the fire thinner tiles are employed, which thin tiles are continued to the end. The two wide passages, *c c*—Fig. 589—beneath the upper pan are covered with iron plates, half an inch thick, on which the pan is placed. It will be understood from this description, that the tiles, or other supporting medium, diminishes in thickness, but increases in conducting power as the distance from the fire increases. This arrangement is necessary, for were iron plates used the whole distance, they would soon be burned through and destroyed in the immediate neighborhood of the fire; and, on the contrary, were thick tiles used for the whole distance, the latter portion of the arrangement near the end of the pan would offer too much resistance to the passage of the heat, and consequently a considerable portion would pass away without being absorbed.

Two such pans are capable of concentrating the acid produced from eight tons of sulphur per week of six days. There are pans at present in use capable of concentrating forty tons of vitriol weekly. Their mode of working is as follows:—The vitriol in the lower pan being of the proper strength, the workman proceeds to run it off into a vessel called a cooler, where it remains until cold. He runs it empty to within two or three inches; when this is accomplished, he proceeds to set a siphon into the upper pan, running the contents into the lower one, which lower one he fills within two or three inches of the top. When the upper pan is empty he refills it with the weak acid from the chamber; he then proceeds to fire the pan until next day, when he will repeat the operations just described.

The other description of pan, the one spoken of as a surface concentrator, is of the following description: Fig. 590 being a vertical section lengthways, the fireplace is at *a*, the flame, *et cetera*, proceeding in the direction of the arrows over the surface of the dilute acid at *b*, when it descends into the flue, carrying with it the evaporated water. It resembles—with the exception of some particular details, to suit the material to be evaporated—the furnace described under the head ALUM in this work, Fig. 89; but in the case of sulphuric acid, the furnace has to be lined, so to speak, with lead; and this lead being liable to fuse at a comparatively low temperature, much ingenuity is

displayed in the methods adopted to prevent as much as possible such an occurrence. One mode of accomplishing this is shown in Fig. 590, where *d d* is a section of the leaden pan, inclosed in brickwork, to prevent

Fig. 590.

the action of the flame. The side of the pan is brought up to the furnace dam, *e*; then within the pan a close row of firebricks, *b*, are placed on end, but not cemented in any way. Thus the sides of the pan are inclosed between brick walls, it only remains to cover up the space, and this is done by placing firebricks on the top, resting partly on the furnace dam, and partly on the row of bricks just mentioned; the flame is thus completely kept off the lead. This is repeated all round, the pan's sides and ends being equally protected. Some manufacturers employ a slightly different arrangement, although on the same principle. A covering brick, expressly made for the purpose, is employed; these bricks are made of the proper size, with an indentation or channel formed in them; this channel being for the purpose of inclosing the

Fig. 591.

upper edge of the pan, side or end. This arrangement is shown in Fig. 591, where *a* is the pan edge; *b*, the brick or tile, with its channel, *c*, inclosing the edge of the pan.

Though these precautions would appear to be sufficient, yet the manufacturer usually avails himself of another invention, which consists in running a stream of cold water round the pan's edge. This is effected by burning or fusing—by means of the hydrogen apparatus mentioned in another portion of this article—to the edge of the pan a leaden tube of a Π shape, the flat side being next to the pan; a section of this pipe is shown in Figs. 590 and 591. This arrangement has a current of cold water constantly flowing through it.

These vitriol pans are often of immense thickness, in some cases the lead of which they are made is an inch thick; but as the heat does not, as in the previously described pans, penetrate through this, it is immaterial. They are worked rather differently to the other pans, inasmuch as it is necessary to cool them to a much lower temperature before running them off. Before this is done the fire must be slackened, or rather put out; for, were the pan to be emptied while the fire was burning with its usual vigor, the pan sides might get so hot as to become soft, and fall or bend down. The upper portion is an arch of firebrick, through which a hole is pierced over one corner of the pan;

through this hole the siphon is inserted for drawing off the finished vitriol; it is also refilled with dilute acid through this. The workman ascertains the progress of the concentration, or its completion, in all cases by taking out a portion from time to time, and placing the vessel containing this trial sample in water to cool. When cold enough, he ascertains the density by means of the hydrometer. When finished it must, as before stated, be of the density of 1.750, or of the strength of 150° on TWADDELL's hydrometer—the instrument most used in this country—when at a temperature of 60°. When of this density, he draws out the fire and proceeds to run the vitriol into what are called coolers, which, as their name indicates, are for the purpose of holding the acid until sufficiently cool to run off into the glass bottles called carboys, for sale or transport to its destination.

These coolers, which are simply shallow lead vessels almost identical with the first-described pans, are, like the latter, formed out of an entire sheet of lead, sometimes half-inch, often of quarter-inch thick. This is, of course, an indifferent matter. The half-inch will last much longer, nevertheless it is not advisable to make them of less than quarter-inch. These coolers are set on iron plates in the manner described with reference to the upper pan; but the ends of the flues are open to the air, which, circulating through these passages, carries off the heat. The sides and ends are held up by brick walls or other convenient supports.

Very good and efficient coolers are constructed as follows:—The dimensions of an iron vessel, capable of holding the quantity of vitriol likely to be run off from the pan, are calculated—these parts are cast of about half-inch thick iron in such a manner that the whole can be securely bolted together. No care is requisite with respect to the accurate fitting of the various joints, as the whole must be lined with say quarter-inch lead. This lead must be turned over the upper edge and flattened down so as to prevent any infiltration of acid between the iron and the lead. If this is not attended to, the acid which finds its way down will act upon the iron, producing protosulphate of iron in masses. These will continue to grow in size, and in so doing will push the lead from the iron, producing misshapen prominences, which will finally destroy the cooler, or rather necessitate the removal of the lead lining, the cleaning the surface of the iron, and finally relining with lead. Two of these coolers, of six feet square and two feet deep, have been in use for some time; they cool the vitriol very rapidly. They are not set on the floor, but on two low walls of brick, so that almost the whole surface of the iron is exposed to the cooling influence of the atmosphere, and the heat is quickly carried off.

It is possible to construct coolers by simply lining a wooden cistern with lead: such are used for crystallizing various salts; but it is a question whether they can be recommended, inasmuch as the cooling must be very slow, on account of the bad conducting quality of the wood which forms the coating to the lead.

In most vitriol works two coolers are used in connection with the pan or pans. Suppose they are called No. 1 and No. 2, the mode of working resem-

bles that of the pans first described; that is, No. 1 is supposed to be cool enough to bear bottling. When this is done, the contents of the upper cooler, or No. 2, is now run into No. 1, while No. 2 is now ready to receive a fresh quantity from the lower concentrating pan. It will thus be seen that in working a set of concentrating pans and their accompaniments, four stages may be recognized. The upper pan partially concentrates the acid ready for the lower pan, which then completes the concentration. From this lower pan it is run into the upper cooler, where it loses the greater portion of its heat, and finally it is run into the lower cooler, where it remains until quite cold or nearly so.

The system just described is in constant use in some works, but is not by any means universal, each manufacturer limiting the extent of his apparatus to his wants. The arrangement most usually seen, especially in small works, is a single boiling-down pan, as it is technically termed; the heat passing beneath it up one flue and returning to the same end down another, after which it passes to the chimney. This pan is accompanied by one cooler. The raw acid from the chamber is run into this single pan, where it is concentrated up to the proper point, after which it is run into the cooler, where it stays until cold; and if the pan is ready to run off again before the vitriol in the cooler is cold enough, there is no help for it, but drawing the fires and letting it stay in the pan until it can be accommodated.

There is no objection to this system except, perhaps, that it is not calculated to do much work; still it answers sufficiently well for small manufacturers.

The manufacture of sulphuric acid has now been traced to the completion of a commercial product, which, in the language of the trade, is called brown oil of vitriol, in order to distinguish it from a product of still higher concentration, to be immediately described. This brown oil of vitriol is used to a large extent by bleachers, calico-printers, dyers, and others; its brown color, from which it derives its name, is due to a certain amount of organic matter which finds its way into it, and which, subjected to the joint action of the acid and heat, becomes carbonized, and colors the whole of a dingy-brown hue. This tint is often augmented from accidental circumstances. Sometimes the workman lets the rag or paper protector, with which he covers his hand while setting the siphon, drop into the pan, at other times fragments of wood-shavings or sawdust find their way into it; when this is the case the vitriol well deserves its name of brown; perhaps, under these circumstances, black would more nearly designate its color. When such an accident occurs, it is usual to destroy this black or brown color by sprinkling a small quantity of some highly oxidizing body into the vitriol while hot in the pan; either nitrate of potassa or soda answers well for this purpose. Finely powdered black oxide of manganese may be used. These bodies yield up sufficient oxygen to the black matter to destroy it, or convert it into some colorless body which does not offend the eye.

Monohydrated Sulphuric Acid—Rectified Oil of Vitriol—English Oil of Vitriol.—Brown oil of vitriol is not sufficiently strong for several purposes; amongst others may be enumerated the manufacture of the dyeing

compound known in commerce as extract of indigo, sometimes called sulphate of indigo. Fuming Nordhausen acid is often directed to be employed in the formation of this body, but in this country it is usual to employ the strongest English sulphuric acid. In order to procure this acid the following methods are adopted:—It has been stated previously that the concentration cannot be safely conducted in lead beyond the density of 1.750, for if driven further, not only would the metal be rather strongly acted upon, but there would be considerable risk of the pan-sides falling in, in consequence of the softening of the lead; so high would the degree of heat become before the last portion of water could be driven off. The further concentration, then, must be performed in vessels made of a material which will withstand the corrosive action of the boiling acid, and which is comparatively infusible. Glass at once suggests itself or some variety of earthenware, such as porcelain, or, amongst the metals, platinum or gold. Of the former two glass offers most advantages, and of the two latter materials platinum is preferable, inasmuch as it resists acids quite as well, and is much cheaper than gold. Glass has been employed in the concentration of vitriol from very early times, perhaps from the period when sulphuric acid began to be understood, and its manufacture attempted on a very small scale, doubtless before the introduction of leaden pans. Platinum, on the other hand, is a comparatively late introduction. The glass vessels employed in the last concentration of sulphuric acid, or, as they are technically known, retorts, resemble very much the bottles or carboys used to transport vitriol from place to place. Their figure is shown in section in Fig. 592, which represents the whole arrangement when at work.

These retorts vary some little in size, manufacturers having lately begun to use much larger ones than were formerly employed. Those in use at the present day are capable of holding more than twenty gallons of liquid, inasmuch as after the rectification or concentration there remains in the retort sufficient vitriol to fill two carboys. This is equal to twenty gallons.

The mode of working can be gathered from the drawing, where A represents the fireplace; the flame, *et cetera*, from the fire plays round the cast-iron pot, C, finally making its exit into the flue, D. On the bottom of the

iron pot just mentioned a quantity of dry sand is laid; and on this the retort, B, is placed, the sand serving as a steady support for it. The retort is not, as is sometimes supposed, surrounded with sand; for, if this were done, it would run some risk of being broken, besides materially retarding the cooling when the rectification was over.

The retort being placed, as in the drawing, it is filled with cold brown vitriol; and when this is done the fire is lighted; the arm, E, is put into its place; the apparatus gradually warms up, and eventually the acid boils; water, with a little sulphuric acid, distils off. This vapor passes off by the stoneware arm, E, into the leaden draught-pipe, F, where a quantity of it condenses; but the greater portion finds its way from thence into the chimney. The contents of the retort are kept boiling for some hours, or until the brown color entirely disappears; for this appears to be the only reaction by which to determine the conclusion of the rectification. It would appear that the organic matter resists the destroying or oxidizing action of the acid, until it has reached its highest point of concentration and temperature. When the clearing has taken place, the fire is withdrawn from beneath the pot; and the whole arrangement is

Fig. 593.

allowed to cool down to a safe temperature, when it is drawn off into carboys. This drawing off is effected by a peculiar siphon, being in fact what is known as MITSCHERLICH'S siphon; but in this case, on a rather large scale, as shown in Fig. 593, it consists of a siphon, with the shorter of its two legs turned back upon itself, as shown at *a*. This turned-up portion should be as short and as close to the siphon leg as possible, in order to be the more easily inserted into the neck of the retort; it is rather exaggerated in the drawing. In order to withdraw the concentrated acid from the retort, the workman first removes the earthenware arm; the siphon is filled with water, the man keeping his thumb firmly closed over the orifice of the longer leg. The shorter leg is inserted into the retort, and gently placed on the bottom; the workman then removes his thumb for a few seconds, until the acid has driven before it the water with which the siphon was charged; when this is done, the end is directed into a carboy which has been placed in readiness by an assistant. When the carboy is full the orifice is again closed by the thumb, while the full carboy is removed and replaced by another empty one. The whole range of retorts are emptied in this manner.

This product is the strongest English sulphuric acid; it is colorless or nearly so, and is of the density 1.850, or 170° on TWADDELL'S hydrometer.

When treating of the commencement of this process, the retort was directed to be filled with cold brown oil of vitriol; it was supposed in this case that the retort was newly starting; but as one charge is now supposed to have been worked off, it will be more or less warm, and the introduction of cold vitriol at this junct-

ture might possibly fracture it. Therefore, it will be necessary to recharge it with warm vitriol, or with vitriol as nearly the same temperature as the retort as possible; and this must be made a rule, if annoyance would be avoided.

It is usual to find in books treating of this matter, the apparatus for rectifying in glass described as con-

sisting of a great number of the retorts, with their accompanying sandpots, *et cetera*, set in a battery, that is, a number of them heated by one fire. Though this may have been the case at one time, it is not the practice or custom to operate in this manner at the present day. Such an arrangement could not have worked as well as the present one, the probabilities being that the

Fig. 594.

retorts which were placed nearest the source of heat, would arrive at their maximum point of concentration some time before those at the end of the arrangement furthest from the fire were finished; in such a case it would have been necessary to have kept on firing until the whole set were done. The result would be that a considerable quantity of sulphuric acid would have distilled off the finished retorts, while those in the rear were being finished. In the present arrangement each retort is by itself, has its own fire, and consequently works totally independent of its neighbors.

The defect of this system of operating is the great fragility of the operating vessel, and the consequent liability to fracture either from a blow or other accident of the kind, or from change of temperature. The room or shed in which a concentrating plant of this description is working, should be closed, and every precaution taken to prevent the access of draughts of cold air or other cooling influence. It is no uncommon occurrence for two or three retorts to be cracked round the top, from the sudden rush of cold wind through an opened door, in such a manner that the whole upper part of the retort could be lifted off; the crack having gone completely round it, and severed the upper portion as completely and as straight along the protecting edge of the sandpot, as though it had been done with a diamond. Mr. JONES of Bristol took out a patent in the year 1845, for a protector to obviate this

accident. The protector consisted of a sort of sheet-iron bell-jar, if such a term may be used; this bell-jar has a hole cut in the upper portion, so that the whole may be placed over a retort when in work, the neck of the retort protruding through this orifice, while the lower edge of this cover rested on the upper edge of the sand-pot. Such an arrangement effectually protects this part of the retorts from cold draughts, or drops of cold liquid, which, as may be easily imagined, are equally destructive. In fact, any cool or cold body coming in contact with the heated glass is fatal to it, causing much inconvenience; for not only is the retort itself destroyed, but the contents are lost, also creating the greatest annoyance and discomfort, for the vitriol trickles or runs out, and, coming in contact with the red-hot pot, is converted into vapor of a most suffocating kind, filling the whole place. This calamity is without remedy; and even though a remedy were to present itself, it would be impossible to enter the place, and apply it, without running considerable risk of suffocation.

These risks and drawbacks were doubtless the stimulants which brought out the platinum retort, this costly, but efficient substitute being safe from the casualties just described. This retort, with its appendages, is shown in Figs. 594 and 595. The former is a vertical section in front; *a*, is the body of the retort; *b*, the head; *c*, a platinum tube leading from the head to a

lead worm, which worm is kept immersed in water; *e* is a platinum funnel, the tube of which is S-shaped, to prevent the return of any vapor. The brown acid which is kept in the cistern, *f*, under which the waste heat passes, is run into the body of the retort without the aid of any tap or valve by means of the at-first sight rather complicated, but really simple apparatus shown in the figure, where *g* represents a round vessel in which a tube, *h*, is inserted very near to the bottom; *i* is another leaden vessel, which has a slit in the side

from the top nearly to the bottom, along which slit the tube, *h*, slides, when the vessel, *g*, is moved up or down by means of the chain and pulley. A siphon, which is kept constantly set, connects the stock cistern, *f*, with the vessel, *g*. The apparatus, when in the inactive state, as represented by the dotted lines, is as follows:—The siphon is full of vitriol, but the surface of the acid in the cistern being on a level with that in vessel *g*, no flow can take place; when the vessel, *g*, is lowered, the levels become altered; and as the leg of

Fig. 595.

the siphon, which is in vessel *g*, becomes the longer, the acid begins to run into this vessel, and from this into vessel *i*, and thence into the funnel.

The other portions of the apparatus being at the back, are shown in Fig. 594, which is a side view; *a*, as before, is the body of the retort; *b*, is a platinum tube about three-fourths of an inch in diameter, in which a glass float is placed to indicate the depth of liquid in the still; *c*, is a siphon, also of platinum, of the same diameter as the tube just mentioned. This siphon is inclosed in an iron tube, *d*; between these two tubes a current of water can be passed. The siphon terminates in a platinum tap at *d*. The body of the still rests on a circular tile of refractory clay; the fire being below this tile, the flame rises at the back of the still, circulates round the sides, and finally passes from thence under the stock-pan. The course is shown in Fig. 595.

The mode of working this still is as follows:—The workman fills up his still a few inches above the highest point the flame is likely to reach; the fire is lighted and kept on until the contents are brought to boiling. The concentration then commences; vapor passes off through the head and conducting tube into the worm, where it again resumes the liquid form, running out into a vessel placed to receive it. This liquid is always acid, but at first it is very weak; it eventually reaches a density of 1.2400. When this strength is attained, the workman knows that the highest degree of concentration is arrived at. If the running-off siphon, *c*, is not set, he proceeds to do this by closing the tap, *d*. The two plugs are removed in the funnel, *f*, and the siphon is filled with vitriol; the plugs are replaced. It

now only remains to open the tap, when the contents of the still begins to run off. The tap is allowed to remain open, until from three to four inches of the still contents are drawn. The workman is guided in this by the indications of the glass float before spoken of, which serves as a gauge. The acid falls into the cup, *g*, thence it flows through the serpentine coil of pipe, *h, h, h*, which is immersed in water; and finally it emerges still slightly warm at the end of the coil, and runs into the receiving vessel, *i*, which vessel stands within another one, a stream of cold water from the tap, *k*, circulating between the two. The water tap, *j*, is also turned, when running off, so that a stream of cold water cools the siphon itself. When the operation is over, the workman proceeds to repeat the course of operations just described; he fills up his still to its former level, attends to his fire, heats it up to the proper point, and again allows the acid to run off.

Such an apparatus, the still itself having a capacity of from seventy to eighty gallons, is capable of producing thirty carboys of rectified oil of vitriol in twelve hours, two carboys being all that a glass retort could produce in twenty hours; but this of course is owing to the latter requiring such a length of time to elapse before its contents can be safely drawn off. A retort of the above dimensions, with the siphon and float case, costs about fifteen hundred pounds, the price varying according to the thickness of metal, and consequently weight of platinum, yet it is generally admitted to be a more economical plan of operating than the glass retort system. But it is not free from disadvantages; it is necessary to be careful that the vitriol contains no nitrous

compound, for if this be the case, the platinum is rapidly attacked. To obviate this, it is usual to add a quantity of sulphate of ammonia to the acid, while in the leaden concentrating pan, before it enters the still; the action of this salt is to decompose the nitrous body usually existing in vitriol. It is supposed that the following is the decomposition which takes place, assuming nitrous acid to be the body present:—

This may occur in some cases, but it is not the invariable result. If a *little* sulphate of ammonia be dissolved in a small quantity of the nitrous vitriol of GAY-LUSSAC'S column, and the whole heated in a test tube, either NO_2 or NO_3 is evolved; nitrogen very probably is given off at the same time, but it is not the only body eliminated. When a rather large excess of sulphate of ammonia is employed, sulphide of hydrogen is formed in the still, and can be detected by the smell at the end of the condensing worm; undoubted evidence of its presence has been detected by means of lead paper. The only rule that can be laid down for guidance as to the quantity to be used, is the addition of an increased quantity of the salt each day until nitrous bodies cannot be detected in the finished vitriol; the workman at last obtains a good idea of the quantity to be added.

Sulphuric acid is brought to a saleable condition by the employment of one or other of the methods just described; but although these methods are universally employed, others have been proposed. The patentee who proposed to generate the steam necessary for the chamber by the combustion of the sulphur, also proposed to concentrate vitriol

Fig. 596.

or any other liquid by means of the heat from this source, hitherto, in the inventor's opinion, wasted. The idea is very ingenious, perhaps more so than practical; but it would appear to be doubtful whether it is possible to concentrate vitriol at all by this process. The probability is that the sulphur

would begin to sublime before the vitriol could be brought to the proper strength. The process is not in use in any part of the country, so that one may naturally infer that it is without practical value.

Perhaps the most ingenious proposal for the concentration of vitriol is the one about to be described, the prevailing principle of which is that of carrying over its surface streams of hot air, which, liberating and combining with the water, carries it off. The apparatus consists of two distinct portions, the one devoted to the production of highly heated air, and the other to the concentration. The former portion of the apparatus consists of a series of iron pipes, *a*—Fig. 597—set in brickwork; these tubes are heated externally by the flame of the furnace, *b*, the products of combustion from which pass up the space, *c*; they then descend and circulate round the tubes, finally making their exit into the main flue by means of the openings, *d*. The cold air

from without enters the lower ends of the tubes which project into the arched recess, *e*, passes up them, and, becoming highly heated during its progress, enters the space, *f*, and passes along the wide iron tube, *g*, and thence into the concentrator. The portion of the apparatus devoted to the concentration is constructed entirely of lead; it consists of two concentric cylinders, *h, h*, made of half-inch lead; *i i*, is a small space, the use of which will be explained hereafter, which exists between them; both cylinders are closed at the bottom by being fused on to one sheet of lead; the inner cylinder is partially closed at the top, space only being left for joining on the leaden tube, *j*, which is a continuation of the iron tube, *g*, spoken of before, and is for the conveyance of the heated air. The inner column or cylinder is filled with coke, or other suitable material, which offers a large surface for the acid to spread itself over, at the same time being unattacked by it. The following is the method of working this apparatus:—The opening into the arched recess from which the cold air is drawn must be closed, or if there be a damper or register beyond the concentrator between it and the chimney, this must be pushed in. The furnace must be heated up until the pipes and the chamber containing them are of a good red heat. This state of preparation having been arrived at, the vitriol to be concentrated must be run on to the top of the inner cylinder; it runs down and fills up the space existing between the two cylinders, rising up to the mouths of and running down the tubes, *k, k*; these tubes are covered with lead caps, the bottom edge of these being immersed in the vitriol from an air-tight joint, which prevents any cold air being drawn in. The vitriol on flowing through these tubes spreads itself over the whole surface of the coke, wetting it thoroughly. When sufficient vitriol has been run in to saturate the whole of the coke, the hot-air current is allowed to enter it, penetrates every space and crevice in the mass, and heating the vitriol up to a high point, carries off its water finally when saturated, making its exit into the chimney by means of the wide tube or pipe, *l*. The vitriol becomes more and more concentrated, the nearer it approaches the lower part of the cylinder. When it has arrived at this point, if the amount of acid and hot air have been proportioned to each other, it will be found to be fully concentrated. It collects in a stratum at the bottom, until the surface rises sufficiently high to flow off into a proper reservoir or cistern through a bent tube, *m*. The use of the double cylinder has two advantages—it heats the sulphuric acid somewhat, previous to its admission into what may be called the concentrator proper; and also keeps the latter cool, or rather lessens the risk of its fusing if too great a heat should be employed.

The apparatus in the form just described, though capable of concentrating vitriol, cannot be said to be a success. The fusion of the lead in the upper portion was the weak point in this invention; in order to work the apparatus with practical efficiency, it was necessary to have the air highly heated, in fact the current of air may be said to have been red hot. Under these circumstances it was almost impossible to avoid the fusion of the lead tube which conveyed the hot air from

the heater. This great difficulty, combined with some minor ones which, however, might be obviated, caused the inventor to relinquish the idea. Although not an

invention or process capable of being carried on in its present shape, yet, in the hands of a patient operator, it might be made to yield better results. It would

Fig. 597.

probably be a work of no little trouble and expense, yet if the anticipated result could be obtained, it would amply repay any trouble or expense that might be expended upon it.

Proposed Improvements in Manufacturing Sulphuric Acid.—The efforts of inventors in connection with sulphuric acid, would appear to have been directed to the substitution of some apparatus of smaller bulk, and less costly in construction, than the leaden chambers ordinarily employed. Perhaps the simplest process embodying the above idea is that of Messrs. M'DOUGALL and RAWSON, who included it in a patent obtained by them in 1848. It consists essentially in passing a stream of sulphurous acid gas through nitric acid by which sulphuric acid and binoxide of nitrogen— NO_2 —are obtained as follows:—

but the great point of the process is the continual conversion and reconversion of this NO_2 into nitric acid, to be again used as before. The inventors say, that the reaction which ensues may be best described by symbols. Thus when 3NO_4 —the NO_2 evolved in the first reaction becoming NO_4 by combining with the excess of oxygen, which as atmospheric air accompanies the sulphurous acid—is passed into water at a temperature of 100° , or upwards, $2 \text{NO}_5 + \text{NO}_2$ results. This NO_5 —or, two atoms of nitric acid—remains in solu-

tion, while the NO_2 , which is an incondensable gas, bubbles through the liquid, and, mixing with the air which is above the liquid, instantly takes two atoms of oxygen from it, and becomes NO_4 ; which, passing again through the liquid, becomes nitric acid and nitrous gas as before: and thus nearly the whole of the nitrous fumes or gas is reconverted into nitric acid. It should be observed that the use of this reaction is claimed in connection with several processes, such as the manufacture of oxalic acid, *et cetera*; but with regard to sulphuric acid, they further say—In our improved method of manufacturing sulphuric acid, we use a series of vessels, similar to that described in the first part of our invention—a modification of Woulfe's bottles, in fact—only that the first vessel of the series is connected with a sulphur burner. The mode of working is to fill the first vessel two-thirds full of nitric acid, and all the others one-third full of water, to charge the burner with sulphur, and then to put in motion the pneumatic apparatus connected with the last vessel of the series. Air is thus drawn over the ignited sulphur, so that sulphurous acid and air pass into a solution of nitric acid in the first vessel, when a portion of the sulphurous acid is converted with sulphuric acid, at the expense of the nitric acid; while the uncondensed sulphurous acid passes into the air, and nitrous gas into the next vessel; and so, as in the first part of the invention, we pass it alternately into water and air, till

the processes of oxidation and condensation are complete. When the working has been continued for some time, we find that the nitric acid has entirely passed from the first vessel, and we have in its place sulphuric acid nearly pure. The same would take place with each of the other vessels of the series, if the nitric acid which has been condensed in the vessels lower in the series, was not again returned to the higher ones, so that when we find the first vessel exhausted of its nitric acid, we remove the sulphuric acid which it contains, and supply it again with nitric acid, obtained from vessels lower in the series. We thus produce sulphuric acid without the loss of nitric acid; as the lower oxides of nitrogen, given off in the oxidation of sulphuric acid, are again converted into the higher oxides, and again used for the conversion of sulphurous acid into sulphuric.

The principle embodied in this process, namely, the perfect recovery of the nitric acid, has been the prevailing idea of many inventors. Some of the other processes to be described are based on the same reaction. About the same time as the date of the above patent, an ingenious modification of their process was being experimented on, of which the following description is an outline:—The apparatus consisted of a burner for the production of sulphurous acid, and an ingenious substitute for the WOLFE'S bottles of the last-described process. The burner, *a*—Fig. 598—consisted of an iron chamber, closed up tight, with the exception of an inlet pipe for the admission of air for combustion, and an exit pipe for the sulphurous acid, proper means being allowed for the introduction of the sulphur. The condensing or the conversion part of the apparatus consisted of two leaden troughs or cisterns; but, as they were exact counterparts of each other, a description of one will suffice. This trough, shown in section in the figure, has, what may not be inappropriately called a false top, *b*, a few inches below the real top, *c*. This false top, which was to all intents a sort of shelf, had borders or edges soldered on to it in such a manner that had it been taken out and laid down with its under side upwards, it would have resembled a large, shallow, square dish. This shelf, as just stated, was fastened inside the cistern, within a few inches of the top, and in an inclined

To work this apparatus the two cisterns were first filled with water or weak vitriol, and the vessel, *d*, was filled with nitric acid; a quantity of sulphur was introduced into the burner, and a coal fire ignited beneath it; a stream of air was then turned on through the tube shown in front of the burner, this stream of air being supplied by a pair of bellows, or other suitable apparatus; when the burner attained a sufficiently high temperature, the sulphur ignited; sulphurous acid became generated; this proceeded along the pipe, *e*, and was discharged beneath the shelf, *b*. At this point it was met by a small stream of nitric acid, which trickled from the vessel, the gases rolled beneath the shelf, and from thence beneath the shelf of the second vessel. The reactions, it is scarcely necessary to observe, must have been precisely the same as those in the last-described process; the gases in this case being kept continually in contact with both air and water, and not alternately, as in the former case.

If, in the instances last given, the recovery and *ad infinitum* use of the nitrous gas has been the object, other methods have been invented or discovered by which the use of this body is proposed to be dispensed with altogether. In this latter class of projects, the oxidation of the sulphurous acid has been sought to be effected by the use of some catalytic agent, no cheap chemical body of an oxidizing character having presented itself capable of successfully rivalling the nitrates. The use of spongy platinum, in consequence of its possessing the requisite property in a high degree, naturally was the first suggestion. PARNELL says this was attempted by Mr. PEREGRINE PHILLIPS. His process consisted in simply mixing the sulphurous acid with excess of oxygen in the shape of atmospheric air, and passing this mixture over balls of spongy platinum at a red heat. The combination took place, and the vapor was received and brought to a liquid state by means of a condenser, like those already described, consisting of a column filled with pebbles, kept constantly wet by a stream of water.

Eventually it was discovered that platinum was not the only body adapted to the purpose; other porous materials, it was found, were capable of effecting the desired union of oxygen and sulphurous acid; for SCHNEIDER states that he has succeeded in converting sulphurous acid directly into sulphuric acid by means of a porous body, for instance, pumicestone, and that this process may be employed for manufacturing sulphuric acid of 170° Twaddell, without the necessity of leaden chambers or of platinum retorts. This has the advantage of being an immeasurably cheaper material although it can scarcely be so active.

M. BLONDEAU describes another process of the same

nature as the last. The author has studied the production of sulphuric acid in certain natural conditions. He instances the Rio Vinagre Pasiambo in

Fig. 598.

position, so that one end was rather higher than the other by about two inches, thus giving it a gentle slope—the use of this will be seen when describing its action.

South America, the water of which, he says, according to an estimate of BOUSSINGAULT, supplies something like thirty-four tons of sulphuric acid in twenty-four hours; and also another instance in which three times this quantity was produced. M. BLONDEAU also examined the production of certain natural sulphates, such as those of potassa, soda, alumina, *et cetera*, and the conditions under which they are produced. Reasoning from his observations, he was induced to try whether certain natural conditions, under which sulphuric acid was produced, could not be imitated in the laboratory; he succeeded in the following manner:—A quantity of argillaceous sand was placed in a porcelain tube laid across a furnace, an apparatus for generating sulphurous acid was attached to one end, together with a tube from a gasometer containing air, and a retort for generating steam. A tube was attached to the other end of the retort, which led into a small vessel containing water, for the purpose of condensing any sulphuric acid which might be formed. The tube was heated red hot, and a slow stream of mixed air, steam, and sulphurous acid was passed through it. At the end of the experiment a quantity of sulphuric acid was found in the condensing flask. M. BLONDEAU suggests this as a mode of making sulphuric acid on the large scale.

WÖHLER has given us the results of some interesting experiments on the production of sulphuric acid by the instrumentality of certain metallic oxides, some acting catalytically, others as simple oxides, yielding up a portion of their oxygen, themselves being converted into lower oxides. He passed a mixture of sulphurous acid and oxygen over several metallic oxides placed in a porcelain tube, and kept at a red heat; but he does not say whether he passed water vapor simultaneously with them. He says that oxide of copper, sesquioxide of iron, and oxide of chromium, each separately employed, instantly caused the production of dense white fumes of sulphuric acid. A mixture of oxide of copper and oxide of chromium, prepared by precipitation, had in particular a very energetic action. The same amount of oxide appeared capable of converting an indefinite quantity of the gases into sulphuric acid. He goes on to say that the production of sulphuric acid proceeds so readily that the process will undoubtedly become practically employed. When sulphurous acid alone is passed over oxide of copper or iron, the first is reduced to red oxide— Cu_2O —and the latter to black oxide— Fe_3O_4 —with production of sulphuric acid vapors; but which, however, cease to appear as soon as the reduction is complete. WÖHLER gives the reaction of several other bodies; he also states that sulphurous acid, oxygen, and water vapor, passed through a tube alone, do not give rise to any sulphuric acid.

These ideas of WÖHLER appear not to have passed without notice, but on the contrary have been most unceremoniously claimed and patented.

Mr. G. ROBB, in a patent which he obtained, March 26th, 1853, proposes passing sulphurous acid and heated air over the surface of heated sesquioxide of iron—sulphuric acid is the product. He proposes also to take up the sulphuric acid as formed, by passing sulphurous acid mixed with air over a mixture of sesquioxide of iron and common salt—sulphate of soda is formed.

ALFRED TRUEMAN obtained a patent for improvements in the manufacture of sulphuric acid when roasting copper ores, *et cetera*. This invention consists in passing the sulphurous acid resulting from the roasting copper ores, mixed with oxygen, atmospheric air, or other suitable material containing oxygen, in contact with heated *platinum, oxide of iron*, or other substance, having in a heated state the property of causing the combination of sulphurous acid and oxygen. The inventor also claims these bodies when diffused in burnt clay, pumicestone, or other suitable body.

Another process proposed for the manufacture of sulphuric acid is that of M. MARGUERITTE. It is entirely different from any yet described; it consists essentially in the separation of the already formed sulphuric acid from sulphate of lime. It is as follows:—Phosphate of lead is decomposed by hydrochloric acid; the phosphoric acid thus obtained is mixed with sulphate of lime, and the mass is calcined, when phosphate of lime remains and sulphuric acid is expelled. The phosphate of lime is decomposed by boiling with the chloride of lead already obtained, when phosphate of lead is again produced; this is again decomposed by hydrochloric acid, and the phosphoric acid set free again employed in the decomposition of a fresh portion of sulphate of lime. In this process the hydrochloric acid is lost in the form of chloride of calcium. It must consequently always be replaced, but when the sulphuric acid produced is employed in the decomposition of common salt for the production of sulphate of soda, the necessary quantity of hydrochloric acid is always reproduced, with the exception of unavoidable losses. By this process sulphuric acid may be separated from sulphate of baryta and other sulphates. He then proceeds to state that, if necessary, quantities of hydrochloric acid may be obtained from chloride of magnesium by heating it to redness when it is decomposed, especially when mixed with clay. This process is, however, not very likely to come into operation; it would require more hydrochloric acid than the author appears to calculate upon. If the composition of bone earth were CaO PO_3 , there would be a possibility of making vitriol by the reproduced hydrochloric acid.

Sulphate of lead has been patented for the same purpose, by decomposing it with strong hydrochloric acid—

Impurities in Sulphuric Acid.—Sulphuric acid of commerce invariably contains lead. It is not difficult to account for the presence of this body when one reflects how much the acid is in contact with this metal in the chambers, concentrating pans, *et cetera*. Lead always makes its appearance as sulphate when strong acid is diluted with water, the concentrated liquid being able to dissolve a portion of this salt which, when diluted, it is not able to retain. Nitrous compounds are found also, together with traces of hydrochloric acid. Traces of selenium have also been detected. Arsenic is a common impurity, derived usually from the iron pyrites, from which much acid is made. Traces of arsenic have also been detected even in vitriol made from commercial sulphur. Sesquisulphate of iron has also

been found to be present. For the great majority of purposes these impurities are not found inconvenient in the arts; while, on the other hand, for some special uses, a process of purification must be had recourse to.

Purification.—When this is required for analytical or other purposes, distillation must be had recourse to. This, in the case of sulphuric acid, is a disagreeable process, not altogether free from danger, from the violent concussions occurring in the retort. It is usual to put a quantity of strips or fragments of platinum into the acid to obviate this bumping. A very simple condensing arrangement is necessary. The beak of the retort merely requires insertion rather loosely into the neck of a flask or wide tube.

For the purification of sulphuric acid from peroxide of nitrogen, nitric, or arsenious acids, Dr. J. Löwe recommends heating it, in the first place, with oxalic acid. This acid, heated with strong sulphuric acid, becomes first dehydrated, and then, as is well known, decomposes. Carbonic acid and carbonic oxide gases are given off. This carbonic oxide, being in the nascent state, has a strong tendency to deoxidize any highly oxidized body; therefore the peroxide of nitrogen and nitric acid give up a portion of their oxygen, becoming reduced to nitrogen, or nitrous oxide—NO—which bodies are not capable of being retained by the sulphuric acid, and therefore fly off. A temperature of 230° is requisite; at this heat the oxalic acid readily decomposes; it is added to the sulphuric acid, to be purified in small proportions in a dry state, as long as the sulphuric acid continues of a yellow tinge, and until a sample allowed to cool fails to show the presence of nitrous compounds, when heated with protosulphate of iron. The same author proposes eliminating the arsenic from sulphuric acid by converting it into chloride of arsenic, which is very volatile. The vitriol is heated in a flat dish, and small quantities of finely powdered chloride of sodium are added, stirring all the while with a glass rod. The arsenic passes off; the following being the reaction, the arsenic existing as arsenious acid:—

The operation must be conducted under a chimney, or other place where the arsenical fumes will be instantly carried off, so as not to injure the operator.

To avoid the troublesome and dangerous process of distillation, AUGUSTUS A. HAYES proposes to purify sulphuric acid in a very simple manner, namely, by crystallizing it. He first adds a small quantity of saltpetre to the acid while hot, in the leaden pan, and at a density if cold of 1·760. This destroys all organic matter, brownness disappears, and the acid becomes clear. A little sulphate of ammonia is now added, to destroy any excess of nitrate, as well as any nitrous compound already existing in it. The acid is now concentrated to a density of 1·780, and run off into deep vessels of lead, which are allowed to cool to a temperature of 32°; they stand so until clear; they are then run off into shallow lead vessels, so placed that they may become refrigerated to 0°. The acid, which has now nearly the composition $\text{SO}_3 \cdot 2 \text{HO}$, would solidify if allowed to remain long enough; but the vessels must stand only until one half the bulk has

assumed the crystalline state; the mother liquid is then poured off. This mother liquid may be used for any ordinary purposes, such as the decomposition of nitrates, common salt, *et cetera*. The crystals are broken up after being washed with pure acid of a former operation, and are fused in a glass or porcelain vessel, when they form pure sulphuric acid.

Detection and Estimation of Sulphuric Acid.—Sulphuric acid is detected by means of a salt of baryta—this earth being capable of separating it from almost any combination, forming with it sulphate of baryta. In some cases, when testing for sulphuric acid, it is necessary to be very cautious; for instance, when endeavoring to ascertain its presence or otherwise in the nitric or hydrochloric acid of commerce, it is necessary to dilute these acids before adding a salt of baryta. If this is not done the nitrate of baryta, or chloride of barium, will itself be thrown down as a crystalline precipitate, liable to be mistaken for sulphate of baryta; but, if so, the addition of water to the precipitate will cause it to disappear, which will not be the case if the precipitate is sulphate of baryta. This latter salt, being very insoluble in water, furnishes us with a correct method of estimating sulphuric acid; for this purpose a weighed portion of the acid or any of its salts is placed in a beaker glass, and diluted with or dissolved in water. If it is a sulphate, the solution should be made *slightly acid* with nitric or hydrochloric acid, but if it is sulphuric acid alone that is being examined this addition is unnecessary; in either case the liquid is boiled, and, while boiling, a solution of chloride of barium or nitrate of baryta is poured in; the whole is allowed to boil a little longer, when it is removed to cool and settle. A little of the clear liquid above the precipitate is then tested, by the addition of a fresh portion of the baryta salt. If a precipitate is produced, it shows that all the sulphuric acid has not been thrown down, in which case it is necessary to add more of the barytic solution and boil again; if, after settling and further addition of baryta, no precipitate is produced, the whole must be thrown on to a filter, washed carefully with hot water, and dried. It is then ignited in a platinum or porcelain crucible and weighed; 116·6 parts, or one equivalent of sulphate of baryta, are equal to forty-nine parts, or one equivalent of monohydrated sulphuric acid, or forty parts of anhydrous acid. This method would be found too tedious to follow, except on special occasions; ordinarily the manufacturer relies on the indications of his hydrometer—that is, he takes the density for his guide. To enable us to arrive at the real value of the sulphuric acid from the density, several tables have been drawn up, of these. Dr. URE's is commonly used.

AMOUNT OF DRY ACID IN SULPHURIC ACID—*Continued.*

SO ₃ HO	Specific gravity.	SO ₃
5	1·0336	4·08
4	1·0268	3·26
3	1·0206	2·45
2	1·0140	1·63
1	1·0074	0·82

In this table there is opposite a list of different densities, the quantity of dry acid per cent., either dry or monohydrated. To bring the degrees of TWADDELL'S hydrometer to those of the real specific gravity, it is only necessary to multiply the first by five, and add one thousand; thus, supposing a sample of vitriol to stand 150° on TWADDELL'S hydrometer, multiply this 150° by 5°, and one has 750°; to this add 1000°, and the specific gravity, 1·750° is obtained. Now, to ascertain the amount of real sulphuric acid in this sample, it is only necessary to run through the table and find the density 1·750°, or the nearest approach to it, which in this case is 1·746°. It will be found then that the sample would contain eighty-three per cent. of the monohydrated acid, or 67·68 per cent. of dry acid.

This method of arriving at the value of a sample, though very convenient, is liable to error; for instance, the sample might contain foreign matter dissolved in it; this would augment the density, and cause it to appear of more value than it really is. A slight change of temperature also will alter the density considerably. The following table, the production of Mr. PARKES, shows the gradual lowering of the density as the temperature increases, so that, even though the sample may be free from foreign bodies, error may creep in. From this table it is evident, that the density of all samples of vitriol should be taken, as in the case of Dr. URE'S table, at as near as possible 60°.

PARKE'S TABLE OF VARIATIONS IN DENSITY OF CONCENTRATED SULPHURIC ACID THROUGH CHANGE OF TEMPERATURE.

Temperature Fahrenheit.	Density.
30°	1·8593
32	1·8563
36	1·8546
38	1·8532
40	1·8527
42	1·8520
44	1·8522
46	1·8519
48	1·8517
52	1·8511
56	1·8500
60	1·8468
63	1·8449
68	1·8435
70	1·8430
74	1·8413
80	1·8381
84	1·8343

Again, when the density of a sample is high, it is difficult to estimate it with sufficient accuracy. If one examine Dr. URE'S table, he will find that acid of 1·8439 specific gravity contains ninety-seven per cent. of monohydrated acid, while the density of the monohydrated acid itself is but 1·8485—thus the slight difference of ·0046, or rather less than one degree on the hydrometer, equals three per cent. To obviate this, Dr. DALTON proposed that the boiling point should be taken as the guide, instead of the specific gravity, inasmuch as it permits a range of ten or twelve degrees for one per cent. of real acid. For this purpose he drew up the following table:—

DR. DALTON'S TABLE OF BOILING POINTS OF SULPHURIC ACID AT DIFFERENT STRENGTHS.

Specific gravity.	Dry acid per cent.	Boiling point.
1.850	81	620°
1.849	80	605
1.848	79	590
1.847	78	575
1.845	77	560
1.842	76	545
1.838	75	530
1.833	74	515
1.827	73	501
1.819	72	487
1.810	71	473
1.801	70	460
1.791	69	447
1.780	68	435
1.769	67	422
1.757	66	410
1.744	65	400
1.730	64	391
1.715	63	382
1.699	62	374
1.684	61	367
1.670	60	360
1.650	58.6	350
1.520	50	290
1.408	40	260
1.300	30	240
1.200	20	224
1.100	10	218

In addition to these methods, there may be mentioned that of testing the value of vitriol by an acidimetric process, with a standard solution of alkali.

Mr. PETER HART, of Manchester, kindly supplied some valuable information which the Editor has incorporated in this monograph.

TARTARIC ACID— $2\text{HO}, \text{C}_8\text{H}_4\text{O}_{10}$ —*Acide tartarique*, French, *Weinsteinsäure*, German—was first obtained in a separate state by SCHEELÉ in 1770. It is found partly free, partly combined with bases in many plants. It exists most largely in grape-juice, but it is met with also in tamarinds, and the berry of the mountain ash; in madder, potatoes, cucumbers, quassia, squills; in mulberries, pine apples, *et cetera*.

Preparation.—In order to prepare the acid, four parts of crude tartar—*argol*—are suspended in boiling water, and one part of chalk added. As soon as the effervescence entirely ceases, and the liquid no longer reddens litmus, the tartrate of lime is allowed to settle at the bottom, and the clear tartrate of potassa decanted. The change which takes place, is as follows:—

The dissolved tartrate of potash may be further decomposed by chloride of calcium: thus—

The well-washed precipitates are digested with sulphuric acid diluted with ten parts of water, five parts of the tartar employed requiring three parts of the acid. Sulphate of lime is formed, and tartaric acid set free. On evaporating the filtered solution in leaden vessels to the consistence of sirup, tartaric acid crystallizes in large, transparent, colorless, oblique rhombic prisms of agreeable sour taste, and specific gravity 1.75; is readily soluble in water and alcohol; unalterable in air. When greatly heated, the crystals become strongly electrical.

Boiled with nitric acid, tartaric acid is decomposed into acetic, oxalic, and saccharic acids. Boiled with hyperoxide of lead, it becomes oxidized and changed into formate of lead, water, and carbonate of lead, thus—

If heated with alkalis, a mixed oxalate and acetate results, with evolution of water, thus—

Mixed with spongy platinum and heated in a stream of oxygen, tartaric acid is at 482° completely resolved into carbonic acid and water.

The action of heat upon tartaric is as instructive as it is remarkable.

It melts between 338° and 356° , and without losing weight is changed into a mixture of two acids—metamerie with tartaric acid.

METATARTARIC ACID— $\text{C}_8\text{H}_5\text{O}_{12}$; or $2\text{HO}, \text{C}_8\text{H}_4\text{O}_{10}$ —forms a transparent vitreous mass. It is bibasic, but its salts are more soluble than the corresponding ones of tartaric acid.

ISOTARTARIC ACID— $\text{HO}, \text{C}_8\text{H}_5\text{O}_{11}$ —is monobasic. Its salts are isomeric with the bitartrates, but very much more soluble. Solutions of isotartrates as well as of metatartrates are changed by boiling into tartrates.

If tartaric acid be heated to 374° it fuses: two equivalents lose one equivalent of water and become changed into an acid, called by FRÉMY, **TARTRALIC ACID**— $3\text{HO}, \text{C}_{16}\text{H}_2\text{O}_{20}$.

If the heat be still longer continued tartaric acid loses half its basic water and becomes **TARTRELIC ACID**— $2\text{HO}, \text{C}_{16}\text{H}_8\text{O}_{10}$.

Most probably both tartralic and tartrellic acids are mere combinations of anhydrous tartaric acid with varied proportions of crystallized tartaric acid.

If the heat— 374° —be carefully maintained for yet a longer time, **ANHYDROUS TARTARIC ACID** or **TARTARIC ANHYDRIDE** remains in form of a white, porous mass insoluble in water. Adherent tartrellic acid is removed by washing with water till the wash liquor no longer reddens litmus. By contact with cold water for a few hours anhydrous tartaric acid resumes its basic water.

Small quantities of tartaric acid are completely decomposed in an oil-bath at 512° , leaving only a slight carbonaceous residue.

Tartaric acid is much used by dyers and calico-printers for the removal of certain mordants from portions of the cloth. It is also used in preparing effervescing draughts. In the blood, tartrates are changed into carbonates.

Aqueous solutions of tartaric acid, especially when hot, exercise right-handed rotation upon polarized rays of light—the angle of deviation corresponds to the quantity of acid traversed by the ray.

Tartaric acid is *bibasic*; its salts are tartrates.

BITARTRATE OF POTASSA— KO , HO , $\text{C}_8\text{H}_4\text{O}_{10}$ —is the *cream of tartar* or *argol* of commerce, and is obtained chiefly as an incrustation from the inside of wine casks. It crystallizes in hard, opaque, oblique rhombic prisms, of snowy whiteness when pure, and of sour taste; soluble in one hundred and eighty parts of cold and six of boiling water; in alcohol nearly insoluble. Heated to redness in close vessels, a mixture of carbonate of potassa and charcoal results—much used as *black flux*. Calcined with its own weight of nitre, *white flux*, or carbonate of potassa, is obtained.

NEUTRAL TARTRATE OF POTASSA— 2KO , $\text{C}_8\text{H}_4\text{O}_{10}$ —by slow evaporation in transparent, colorless prisms, somewhat deliquescent, and very soluble.

BITARTRATE OF SODA— NaO , HO , $\text{C}_8\text{H}_4\text{O}_{10}$, 2HO —in transparent, colorless, right rhombic prisms, from a hot solution of the neutral salt, mixed with half its weight of tartaric acid.

NEUTRAL TARTRATE OF SODA— 2NaO , $\text{C}_8\text{H}_4\text{O}_{10}$, 4HO —soluble in five of cold and half their weight of boiling water. In transparent, colorless, right rhombic prisms.

NEUTRAL TARTRATE OF POTASSA AND SODA— KO , NaO , $\text{C}_8\text{H}_4\text{O}_{10}$, 8HO —is *Rochelle salt*, obtained by neutralizing cream of tartar with carbonate of soda. In large, transparent, colorless, right rhombic prisms, soluble in 2.62 parts of water at 42° . The salt is medicinal.

BITARTRATE OF LITHIA— LO , HO , $\text{C}_8\text{H}_4\text{O}_{10}$, 3HO —in small crystals, very soluble in water.

NEUTRAL TARTRATE OF LITHIA— 2LO , $\text{C}_8\text{H}_4\text{O}_{10}$ —white, opaque, deliquescent.

BITARTRATE OF AMMONIA— NH_4O , HO , $\text{C}_8\text{H}_4\text{O}_{10}$ —in delicate needles, but little soluble in water. The crystals are in form of oblique rhombic prisms.

NEUTRAL TARTRATE OF AMMONIA— $2\text{NH}_4\text{O}$, $\text{C}_8\text{H}_4\text{O}_{10}$ —in oblique prisms, readily soluble, and with a taste like that of nitre.

NEUTRAL TARTRATE OF POTASSA AND AMMONIA— KO , NH_4O , $\text{C}_8\text{H}_4\text{O}_{10}$ —in transparent, colorless prisms, isomorphous with neutral tartrate of potash.

NEUTRAL TARTRATE OF BARYTA— 2BaO , $\text{C}_8\text{H}_4\text{O}_{10}$ —a crystalline powder, soluble in eight hundred parts of cold water.

NEUTRAL TARTRATE OF STRONTIA— 2SrO , $\text{C}_8\text{H}_4\text{O}_{10}$, 8HO —soluble in one hundred and forty-seven parts of water at 60° .

BITARTRATE OF LIME— CaO , HO , $\text{C}_8\text{H}_4\text{O}_{10}$ —in the fruit of *Rhus typhinum*, in crystals, sparingly soluble in water.

NEUTRAL TARTRATE OF LIME— 2CaO , $\text{C}_8\text{H}_4\text{O}_{10}$ —occurs in grapes, and mixed with crude tartar; also in senna leaves. Neutral tartrate of potassa forms, with chloride of calcium, a crystalline precipitate—it is the salt obtained in making tartaric acid. Crystals, right rhombic prisms with octahedral summits; soluble in twelve hundred parts of cold water.

BITARTRATE OF LIME— CaO , HO , $\text{C}_8\text{H}_4\text{O}_{10}$ —in the fruit of *Rhus typhinum*. The crystals dissolve in one hundred and forty parts of water and reddens litmus.

NEUTRAL TARTRATE OF MAGNESIA— 2MgO , $\text{C}_8\text{H}_4\text{O}_{10}$, 8HO —obtained by digesting excess of magnesia alba in dilute tartaric acid. Crystalline crusts

soluble in one hundred and twenty-two parts of cold water. Like tartrate of lime, the residue by ignition is pyrophoric.

BITARTRATE OF MAGNESIA— MgO , HO , $\text{C}_8\text{H}_4\text{O}_{10}$ —when excess of acid is employed. Six-sided prisms soluble in fifty-two parts of cold water.

TARTRATE OF ALUMINA occurs in *Lycopodium clavatum*. Very soluble.

TARTRATE OF LEAD— 2PbO , $\text{C}_8\text{H}_4\text{O}_{10}$ —by precipitating neutral acetate of lead with tartaric acid. A white crystalline powder, almost insoluble in water.

PROTOTARTRATE OF IRON is made from iron filings and dilute tartaric acid, with exclusion of air. A white powder requiring four hundred and twenty-six parts of cold water for solution. It is said to contain thirteen per cent. of water.

PERTARTRATE OF IRON, by dissolving the freshly prepared hydrated peroxide of iron in solution of tartaric acid. Its solution is not precipitated by alkalis.

POTASSO-TARTRATE OF IRON— KO , Fe_2O_3 , $\text{C}_8\text{H}_4\text{O}_{10}$ —is an important medicinal salt. It is obtained by digesting the hydrated sesquioxide of iron with water, and bitartrate of potassa at 125° for twenty-four to thirty-six hours, and evaporating the residue on plates. In lustrous scales of dark brown color.

AMMONIO-TARTRATE OF IRON— NH_3 , Fe_2O_3 , $\text{C}_8\text{H}_4\text{O}_{10}$, 4HO . Made like the previous salt, with substitution of bitartrate of ammonia. It is quite stable in composition when its solution is boiled.

TARTRATE OF COPPER— 2CuO , $\text{C}_8\text{H}_4\text{O}_{10}$, 6HO —by precipitation of acetate of copper with tartaric acid. A very light blue powder, soluble in one thousand seven hundred parts of cold water.

POTASSO-TARTRATE OF COPPER— KO , CuO , $\text{C}_8\text{H}_4\text{O}_{10}$ —by boiling oxide of copper in solution of cream of tartar. Crystals dark blue; very soluble.

TARTRATE OF SILVER— 2AgO , $\text{C}_8\text{H}_4\text{O}_{10}$ —by mixing neutral tartrate of potash or Rochelle salt with nitrate of silver. A white, crystalline, lustrous powder; gently heated, spongy silver remains, with evolution of pyrotartaric and carbonic acids.

POTASSO-TARTRATE OF ANTIMONY— KO , SbO_3 , $\text{C}_8\text{H}_4\text{O}_{10}$, HO —is extensively used in medicine under the name of *tartar emetic*. Three parts of oxide of antimony are made into a thin paste with water, and mixed with four parts of bitartrate of potassa. The mixture is digested for several hours, and then boiled with eight parts of water. The boiling-hot solution is filtered and allowed to crystallize. Transparent or opaque, colorless, shining rhombic octahedra, of metallic taste. It is soluble in fifteen parts of cold and two of boiling water. In small doses it is an emetic; in larger doses it is a poison.

Of the heavy metals, iron is the only one which precipitates antimony completely from the aqueous solution of tartar emetic. Hydrochloric, nitric, and sulphuric acids precipitate a basic hydrochlorate, nitrate, and sulphate of the oxide of antimony.

There are several other antimonial tartrates, the place of potassa being supplied by soda, ammonia, lead, oxide, and silver oxide. A compound similar to tartar emetic may be formed with arsenious acid— $(\text{KO}, \text{AsO}_3, \text{C}_8\text{H}_4\text{O}_{10})$.

TIN.—*Etain*, French; *zinn*, German; *stannum*, Latin.—Tin is the *Jupiter* of the alchemists. It is one of the metals which were known to the ancients, and is evidently of high antiquity, although, in all probability, gold, silver, copper, and iron were known much sooner. It is supposed by some that the original Hebrew term *bedil* of Holy Writ indicates this metal; but others infer that a compound or mixture resulting, perhaps, from the purification of gold and silver possessing an inferior value, was meant by it. Under the impression that the word above mentioned denoted tin, the Greek translators of the scriptures rendered it *κασσιτερος*, by which term the classic writers of profane history describe tin, after all doubt had been removed as to its identity. BECKMAN discusses the question whether the *stannum* of the Latins and the *κασσιτερος* of the Greeks was really the metal which forms the subject of the present article; and whilst he leaves the point undecided, advances various arguments to show that a rich alloy of silver and lead was frequently, if not always, the substance indicated by the foregoing titles.

Whatever may have been the nature of such alloys, it is certain, from the writings of DIOSCORIDES, DIODORUS, PLINY, and others, as well as from Celtic records, that tin was known at a very early period. It is recorded that between 1040 and 1030 before the Christian era, the Phœnicians had discovered that part of Britain known at present as Cornwall and Devon, and instituted searches for minerals and metals therein; and the active exportation of the metals—principally tin—led to the adoption of the title *Breotan*—red or burning fires and land—for the mainland, from the circumstance of large fires being kept burning on all the bold heights of the country to serve as beacons for the mariners along the dangerous coast; of which words Britain is but a slight modification. The metal tin was called in the dialect of the people of Phœnicia *stān*, whence the *stannum* of the Romans; from this root likewise has been derived the title *Stanneries*, which is still applied in Cornwall to the districts where tin is produced.

That the quantity of tin extracted from the British mines was considerable, is very evident even from the account of the Greek writers already alluded to; thus DIODORUS, in the second chapter of his fifth book, says—The inhabitants of that part of Breo-tan—Britain—called Bolerion—supposed to be the Land's-end, but actually a corruption of *Bal-erig*, which means the country of the *Erians* or *Iberians*, of which it is an abbreviation—excel in their hospitality; and also, from their converse with merchants, they are more civilized and courteous to strangers. These are the people who make the tin, which, with a great deal of care and labor, they dig out of the ground which is rocky; but it has in its earthy veins, the produce of which is brought down, melted, and purified. Then when they have cast it into the form of cubes, they carry it to an island adjoining to Britain called Iktis. During the recess of the tide the intervening space is left dry, and the tin is carried to the island in carts; and it is something peculiar that happens to the islands in those parts lying between Europe and Britain, for at full tide, the passage being overflowed, they appear islands; but when the

sea returns, a large space is left dry, and they are seen as peninsulæ. From this the tin is transported to Gaul, through which it is conveyed on horseback in about thirty days to the mouth of the river Rhone.—*Diodorus*.

The island above alluded to will be at once recognized as one of the Scillies, and its Greek name was probably derived from its being made a fishing-station by the Phœnicians.

Of the mode of operations by which the tin was extracted, or the mines worked in those days, no record is left; but from the remains which have been discovered, it is conjectured that the methods adopted were of the rudest description. By whatever means the mining and metallurgy of tin were prosecuted in Cornwall and Devon up to the period of the Norman conquest, it is certain that after that event they received a great impetus, so that the chief part of the revenues of the Earls of Cornwall was derived from it. King John gave a charter to the Cornish tin mines in 1201; another was granted them in 1305 by Edward I., and the stannery laws were instituted in his reign. These laws are still extant, and partly in force; but want of space forbids a full account of them here. Previous to the thirteenth century England enjoyed a monopoly of the tin trade; but in that age rich veins of tin ore were discovered in Misnia and Bohemia; and about the year 1250 the English trade was much reduced by the low price at which the Germans were able to sell their tin. At present tin is found in several places, and mines of it are wrought in Bohemia, Saxony, and Austria; in Galicia, on the borders of Portugal; at Piriac, in the *Loire inférieure*; and at Vaulry, in the department Haute Vienne in France; but the mines of French localities are of very little importance. Large quantities of tin ore occur in the Siberian mining district of Nertschinsk, and it is found in Dalecarlia in Sweden; but the richest deposits that have hitherto been found are those in the province of Tenasserim on the east side of the Gulf of Martaban in the Malayan peninsula; these have been worked for many centuries, and considerable quantities are still obtained. In the early part of the last century—1710—large quantities of very pure ore of tin were discovered in the island of Banca, whence as much as three thousand five hundred tons of the metal have some years been abstracted. Minerals of tin exist also in Brazil, in Mexico and Chili, in South America, in the United States, and Australia. The tin mining districts of Cornwall and Devonshire are three in number; namely, that included in the South-west of Cornwall beyond Truro, the neighborhood of St. Austell, and of Tavistock in Devonshire. The chief tin mines in these districts are Wheal Vor, near Helston; Polberrow, near St. Agnes; Polgooth, near St. Austell; Drake Walls, near Tavistock, on the Cornish side of the Tamar; and Birch Tor, also near Tavistock, but on the Eastern side in Devonshire. Ores of tin are found in all the localities mentioned, either in the form of regular lodes or veins disseminated in granite and in felspar—porphyry or elvan—and in alluvial formations on the slopes of hills, or in the valleys. In the former instances, the veins frequently cross one another either horizontally or in their perpendicular descent; occasionally they ramify through the rock in all directions,

producing at the point of intersection masses of ore called by the Germans *stockwerk*, such as the Altenberg mine in Saxony. In the other instance of the occurrence of tin ore, namely, in alluvial deposits, it is usually called *stream tin*, as well from the nature of the deposit, as from the fact that in these cases the workings are generally in the course of rivulets or streams. It is found either in a pulverized sandy state, in separate stones, called *shodes* in Cornwall, or in a continued course of stones, which are sometimes found together in large numbers, and at depths varying from one to fifty feet. The course of these deposits is called a stream; but they have little regularity, varying in their breadth, and are scattered over the entire extent of the moor or valley in which they are found. *Wood tin*, the name given to pebbles of ore having a woody appearance, though now rather scarce, was formerly found in some of the stream-works of Cornwall.

MINERALS OF TIN.—Tin is found almost invariably in the form of binoxide of tin or tin-stone, and in some instances associated with iron and copper pyrites, forming what is called tin pyrites or bell-metal ore, but the quantity so existing is very small.

BINOXIDE OF TIN—*Cassiterite*; *tin-stone*; *zinnstein*.—This ore of tin, from which almost the whole of the metal is smelted, is found, as already mentioned, in different states of aggregation. It is characterized by a high gravity, averaging 6·3 to 7·1, adamantine lustre, and color varying from a brown or black to various shades of red, yellow, grey, and white. In crystalline shape it belongs to the right prismatic system, the crystals being twins, with some of the faces uneven, and others striated parallel to their intersections with each other. The crystals have but a very imperfect cleavage, their fracture is imperfectly conchoidal and their streak grey, and sometimes brown. Heated before the blowpipe, oxide of tin remains infusible *per se*; with soda in the reducing flame it affords small globules of metal. Acids do not exert a solvent action upon it, and therefore it cannot be dissolved till after its fusion with alkalis. In its pure state binoxide of tin contains—

	Atomic weight.	Centesimally.
1 Eq. of tin,	59	78·66
2 Eqs. of oxygen,	16	21·34
	75	100·00

Samples of the ore have been analyzed, and the results are stated thus—

	From Altonon in Cornwall, by Klaproth.	From Schlacken- wald, by Klaproth.	From Finbo, near Fahlun, by Berzelius.
Oxide of tin,	98·93	99·28	93·6
Red oxide of iron,	0·32	0·72	1·4
Silica,	0·75	—	—
Columbic acid,	—	—	2·4
Binoxide of manganese	—	—	0·8
	100·00	100·00	98·2

This ore is found in the various localities already referred to, accompanied with quartz, mica, fluorspar, apatite, topaz, tourmaline, wolfram, heavyspar, mispickel in the lode; and in the alluvial beds of valleys and plains.

TIN PYRITES—*stannin*; *zinnlicies*.—This ore of tin occurs in a few of the Cornish mines, such as those

of Huel Rock in St. Agnes, and some of the granite veins in St. Michael's Mount; also at Zinnwald in Bohemia. Its crystalline form is cubic; the cleavage of the crystals is imperfect, the fracture uneven and conchoidal, the lustre metallic, with a steel-grey, inclining to bronze-yellow color, and a black streak. The specific gravity is 4·3 to 4·51.

Before the blowpipe on charcoal it melts in a strong heat, turns white on the surface, and deposits a fixed sublimate of binoxide of tin round the assay. After roasting, it affords, with the usual fluxes, the peculiar reactions of iron and copper, and a brittle globule of the latter metal on fluxing with soda and borax. Nitric acid decomposes it, dissolving the iron and copper, and leaving a deposit of sulphur and of binoxide of tin. The following analyses indicate the composition of a few samples of this ore; samples A and B from Huel Rock; C from St. Michael's Mount, and D from Zinnwald:—

PREPARATION OF TIN.—The reduction of the ore is effected by roasting and smelting, in a manner similar to that which will be described further on, and the button so obtained is then treated in the following manner, to separate the metal from the arsenic, antimony, bismuth, zinc, lead, iron, and copper, one or more of which it may contain; or ordinary commercial tin may be taken for this purpose.

In either case the crude metal is treated with an excess of hydrochloric acid, when the tin, zinc, bismuth, copper, and iron are dissolved, whilst the arsenic and antimony will be separated; the former volatilized in the form of terhydride of arsenic, and the latter partly deposited as a black powder in the liquid, and partly dispelled as antimonide of hydrogen. The solution is filtered, and the liquid concentrated at a boiling temperature, and strong nitric acid in excess added, after which the evaporation is continued to dryness. The tin is thus obtained in the state of binoxide, which should be treated with a little hydrochloric acid, then filtered, washed thoroughly, and dried, mixed with charcoal, and reduced at a white heat in a charcoal-lined crucible.

Properties.—Tin is a white metal, having a metallic lustre, approximating to that of silver; it is softer than gold, but harder than lead, and has a specific gravity of 7·291. It is very malleable, so much so that it can be rolled into sheets of not more than the one-thousandth of an inch in thickness, but wanting ductility and tenacity to any useful degree. A wire of the metal, 0·7 of an inch in diameter, will sustain only thirty-four and a half pounds weight. Tin melts at 442°, and contracts slightly on cooling; at a strong red heat it emits white fumes, but the tension of its vapor is

very feeble, and therefore little loss of metal is sustained. The metal exhibits a great tendency to crystallize when a mass of it is melted in a covered crucible, and allowed to cool very slowly; if before the bulk has solidified the fluid portion be poured off, the hardened part remaining in the vessel will be found crystallized in rhombic plates, according to PAJOT; and in octagonal needles, according to BROOKE. This tendency to crystallize is readily exhibited by dissolving the exterior coating of a plate of the metal by means of moderately dilute aqua-regia, and then washing off the acid with water. The surface will then exhibit a mottled appearance, owing to the irregular reflection of the fern-like crystals which the action of the acid reveals. Various pretty designs are in this way formed on the surface of moderately thick tinned plates; and the French, who practise the process for decorating snuff-boxes, *et cetera*, call it *moiré métallique*. It is to the crystalline arrangement of the particles of the metal that the crackling sound which a bar of it emits on being bent backward and forward is due, the decrepitation being produced by the displacement of the small crystals of which the bar is composed. By repeatedly inducing this friction an amount of caloric is developed, which can be readily detected by a sensible calorimeter.

Tin retains its brilliancy for a considerable time when exposed to the air; when heated in the air to the melting point, however, it is immediately covered with a film of oxide of tin; and if the heat be increased, the oxidation of the metal becomes so rapid as to induce ignition. In both instances binoxide of tin results. The same change takes place when steam is passed over a bath of the metal heated to redness out of contact of air; for the metal abstracts the oxygen of the water, and sets free the hydrogen. Tin combines with most of the metalloids, producing generally two orders of combination, distinguished by the terms proto or stannous, and binary or stannic, compounds of such elements with the metal. The combination with many of these, as with sulphur, bromine, iodine, chlorine, *et cetera*, is so intense that, at a slightly elevated temperature the metal enters into active combustion, whilst the stannic salts of these radicals are produced. Acids have likewise a well-marked action upon it; for instance, hydrochloric acid, at the ordinary temperature, slowly dissolves it, with evolution of hydrogen; at a boiling temperature the action is much more active; in both reactions the stannous chloride is formed. Dilute sulphuric acid, with the aid of heat, converts it slowly into a sulphate of the protoxide, and liberates hydrogen; the concentrated acid has little or no effect upon it in the cold, but if the liquid be heated to the boiling point, it rapidly attacks the metal, sulphurous acid being liberated. Slips of bright tin-foil, immersed in concentrated nitric acid, experience no change, however long they may be

retained in it; but if the acid be diluted with water, the action becomes violent, owing to the rapid conversion of the metal to a binoxide of modified properties, known as metastannic acid, and the evolution of binoxide of nitrogen. If the nitric acid be previously diluted, no nitrous fumes are given off during the oxidation of the metal, but nitrate of ammonia is formed, thus—

The fixed caustic alkalis dissolve tin, and produce with it a compound in which the combination of this metal takes the character of a salt radical; in this case water is decomposed and its oxygen is assimilated by the tin, whilst the hydrogen is given off.

The symbol for tin is Sn; its equivalent number 59.

METALLURGY OF TIN—Preparation or Dressing of the Ore.—In preparing ore of tin for the smelter, much pains are taken for the separation of all earthy matters and metallic substances that would reduce the percentage yield of the ore, or injure the quality of the tin when smelted. The order in which this dressing is performed is much the same as when copper ores are under treatment—namely, *cleaning* and *sorting* of the ore, *stamping* and *washing*, and, finally, *calcination* and *washing*.

Sorting the Ore.—This operation is commenced on the surface by washing away the clay and light impurities from the ore by a stream of water, and breaking or *spaling* the stones containing the ore, and separating the whole into heaps of different qualities and classes, according to the nature of the gangue, or the other minerals accompanying the tin; thus ores containing copper and iron pyrites are classed differently from such as contain only earthy matters, and such as contain tungsten are set aside by themselves to be submitted to a special treatment. The richest and

Fig. 599.

purest lumps are placed together in heaps on the dressing floor, and are called *best work*; the second quality, though less rich than the preceding, are

nevertheless remunerative; and the third division consists of matter that is very poor in, if not wholly without, ore.

The several heaps of ore are further reduced by the stamping mill to a fine powder. This *machine* is shown in section in Fig. 599. It consists of a wooden shaft, connected with a water-wheel or steam-engine, in which are arranged a number of cams that catch upon the lifting arms of a series of pestles heavily shod with iron, and secured in a strong wooden box lined with iron to prevent the dispersion in all directions of the ore by the strokes of the pestles or stamps. In the figure, A indicates the revolving shaft with the cams, B the pestle, and C the box confining them, D the ore to be crushed, and E a sluice which supplies a stream of water that carries off the reduced ore to the tanks along narrow inclined planes. Four stamping heads, averaging two and a half to three and a half hundredweight each, are worked in each box, and in the following order:—The pestle to the left of the spectator, supposed to be standing in front, first; the extreme right second; the right middle one third; and the left middle last—and each pestle is so lifted that the strokes follow in succession. The revolving shaft makes about twenty revolutions per minute, and the ore which enters the box receives from one hundred and sixty strokes to double this number to reduce it. The stream of water, entering the box from E, conveys the reduced ore, aided by the force of the pestles, through gratings at the ends and sides of the box to the inclined plane or cistern already mentioned. Here the ore, in consequence of its gravity varying in the ratio of its contents of metal, arranges itself into three kinds—the heaviest, and therefore the richest, resting on the upper part; a less rich ore in the middle; and the poorest or gangue parts—the tailings—at the lowest part. Very fine portions of the ore are carried off by the water in suspension to the slime pits, where it settles to the bottom, to be occasionally collected. The richest portion of the ore on the inclined plane is removed to the rectangular *buddle*, where it is washed under a regular stream of water, the ore being kept by a brush spread equally over the floor of the buddle. In this way the material is further purified, the richer ore remaining on the upper half of the table, and a poorer product on the lower half.

The richer ore is further purified in the *kieve*, or tos-

Fig. 600.

sing tub—Fig. 600. It consists simply of a stout wooden vat, well bound with iron hoops, having a capacity of a hundred gallons or more. A quantity of the purer

ore, from the buddle in the preceding instance, together with a quantity of water, is thrown into the tub and stirred well up with a shovel for a few minutes, and then allowed to rest, while to expedite the subsidence of the ore, the workman strikes the tub all round with a hammer. Here, again, a further separation of the ore takes place, according to the order of its gravity, the richer kinds being nearer the bottom of the tub, and forming distinct layers, as shown in the figure. The top layer is thrown away as being of little value, or is reserved for further washing in the circular buddle with other portions of poor ore; the second is submitted to another washing; and the lower layer is fit for the smelting furnace or the roaster, if it be pyritous, and is called *tin witts*.

The matter on the middle of the inclined plane or cistern adjoining the stamping mill is delivered into a wooden trough placed over the cistern, and washed by a small stream of water direct into the circular buddle, where the washing of ore is effected in larger quantity, and at less expense than in washing the rich ore as it becomes separated. Several of these circular buddles are required, and the lower layer of the deposit in one is conveyed by a trough to the next, and there washed. In this way the richer parts are removed from the poorer tailings; and when they arrive at the proper standard they are removed, and their cleansing finished on the rectangular buddle and tossing tub, as described. The contents of the slime pits are purified, first, by what is known as the *trunking process*, and secondly, on the *racking table*. The trunking box consists of a long sloping cistern, with a division near its upper end, forming a small quadrangular vessel, in which the ore, slime, and water are delivered. The contents of this small cistern are agitated by the slow movement of a paddle placed in it, and thus portions of slime and water are thrown out into the sloping trunk at each stroke. As it flows down this incline the heavier ore first separates, and continues to deposit, according to its density, towards the end of the trunk, where, however, the matter collected is of little worth. When enough of the mud is thus treated to fill the long cistern, the admission of more of the sludge is prevented, and the higher portion of the deposit is transferred to the *racking tables*, whilst the other portion is again submitted to the preceding trunking process. The racking table, shown in Fig. 601, is a long wooden table, set at an incline of one in sixteen, and having shallow bevilled flanges at the sides and ends to serve as a frame for it, and supported by centre pivots on a wooden framework about three feet high. At the head of the table is fixed the sloping board, hinged to it with leather, and upon this the mixture of ore and water is delivered, and a number of boxes, generally three, are fixed beneath it to receive the different qualities of the washed product.

About twelve or fifteen pounds of the selected stuff from the trunk boxes are placed on the fixed head and washed over the hinge board to the table. It is equally distributed over the board with the aid of a rake or brush, when the water sweeps along the lighter portions, and carries the worthless matter through a

narrow slit at the bottom of the table into a gutter. The selected and rich deposit on the table is washed out into the receptacles beneath it by inclining the latter to one side, and a fresh quantity operated upon

Fig. 601.

as before. The contents of the first, second, and third box are washed again on the rack once, twice, or thrice, as it is deemed necessary, before the product of the first vessel is sent to the tossing tub.

Stream tin is dressed by a similar course of operations as the foregoing, only that the ore is first treated in a large trunking box, where the workmen separate by a rake the larger from the smaller particles of ore. After this, the divisions of ore are submitted to a picking, stamping, and washing operation, mostly like that detailed above. With stream tin these processes serve to produce a very pure ore, devoid of most of its earthy components, and ready for the smelter; but when the tin is found in lodes, associated with copper and iron pyrites, the dressing course with simple washings is insufficient to remove the sulphurous compounds, and with which the ore cannot be smelted.

To remove them, the ore from the tossing tub—the *tin witts*—is conveyed to the burning house, and roasted in reverberatory furnaces, or in a kind of roaster called from its inventor BRUNTON'S calciner. The reverberatories are of the usual form, having a bed about nine feet long, five feet wide in the middle, and four feet at the back part, wherein is situated the working door. The charge, amounting to ten or twelve hundredweight of ore, is let down upon the bed through a hopper in the arch, and when roasted it is drawn out to an arched space beneath the bed by a small aperture inside the working door in the latter. The temperature supplied should not exceed a dull red heat, such as will be capable of dispelling the arsenic and sulphur without fusing the sulphurous compounds. Frequent rabbling of the ore on the bed of the furnace expedites the separation of the sulphur and arsenic; but, under all the attentions given, the time for each charge averages, according to the amount of impurities, from eight to twelve hours. The arsenical and sulphurous vapors pass from the furnace into a wide flue, which is divided into a series of compartments or chambers of varied dimensions, for the purpose of arresting the arsenic, and leading to a low chimney usually erected on some adjoining and commanding eminence.

BRUNTON'S calciner is shown in Fig. 602. It is a circular cast-iron table fixed on a stout central shaft,

placed in proper bearings beneath the furnace, so as to permit its turning slowly with the table, C, which is set in motion by a small pinion gearing into a toothed wheel fastened to its under side. This table is fixed beneath the dome of a reverberatory furnace, having a hopper, E, for retaining the ore to be calcined, and in which the upper end of the central shaft turns and distributes the ore on the plate in a continuous stream. The fire is at A, and the products of its combustion pass over the ore to the flue, B, leading to the chimney. Owing to the revolution of the bed of the furnace the ore is kept constantly turned and moved till it travels to the circumference whence it is ejected through the apertures, H, into the receptacle or *wrinkle*, G, in the same ratio that it is supplied from the hopper. Power is communicated to the gearing pinion by a water-wheel or

other means; and the rate at which the ore is to pass over the calciner is regulated by the quick or slow motion of this shaft. Much labor and fuel are said to be economized by the adoption of this system of roasting.

The roasting effects the conversion of the dense metallic sulphides into friable and light oxides, which, being of a less gravity than the tin ore that remains unaltered by the operation, can be readily separated by a proper system of washing. The several kinds of products from the preliminary dressing, such as jigged, fluran, smalls, slime, and roughs, are burned separately,

Fig. 602.

and each subjected afterwards to a particular treatment; thus the jigged parcels are simply jigged again on a copper sieve after the burning; the fluran is passed through the buddle and tie, and the finer divisions are submitted to more complicated processes, consisting of *buddling*, *tossing*, *packing*, and further washing of the residues from these operations on hair sieves, till finally

the tin crop remains as pure as possible. Numerous divisions of tin ores are made according to the quantity of the accompanying bodies and their nature, besides those already alluded to; and their dressing gives rise to several refuse matters, the purification of which necessitates a complication of operations, which are varied according to circumstances and the judgment of the superintendent of the mine. The *burned leavings* from the foregoing operations, containing more or less tin, are restamped with some silicious matter and rewashed; the crushing with the sand, *et cetera*, detaches from the particles of tin the earthy matters that were combined with them, and that rendered them specifically lighter in the preceding washings. They may now be readily separated by a stream of water in the trunking box or buddle, and the tin obtained.

Improvements in the Dressing of Tin Ore.—Several improved methods of purifying ores of tin have been suggested and practised during the last quarter of a century. The principal of these consist in the use of acids for the separation of the injurious matters from the tin ore, which remains unacted upon by them. By the use of hydrochloric and sulphuric acids the fragments of metallic iron from the tools of the miners, of oxides of iron, copper, *et cetera*, are dissolved and removed from the tin by simple washing, much more effectively, than could be done by any mechanical operation, however carefully performed. Acids have been in use for the dressing of tin ores since 1842, or earlier; muriatic acid being preferred where the impurity is iron and its oxide, and sulphuric acid for the separation of the copper existing in the roasted ore as oxide, which is afterwards thrown down from its solutions by metallic iron or zinc, and the sulphate of iron, or of zinc recovered. LONGMAID'S patent process of separating the sulphur from pyritic ores by fusing them with common salt, whereby the sulphur is converted into sulphate of soda, and the copper into the form of chloride, could be applied to the purification of tin ores containing the foregoing additional metals. Washing the roasted mass would remove the copper salt, and the sesquioxide of iron would be carried off in mechanical suspension, leaving the oxide of tin in a partially pure state behind. The preceding methods of treatment do not serve to purify ores of tin associated with *wolfram*—the double tungstate of iron and manganese—for this mineral has a density averaging 7.1 to 7.4, and therefore so closely approximating to that of tin that no amount of mechanical washing could part the two satisfactorily. Before the process for its purification was discovered, the tin obtained from this kind of ore was very inferior, and consequently the ores themselves were greatly depressed in value. By OXLAND'S method of removing the tungstic acid from them, however, they are so improved that first quality tin can be smelted from them, and necessarily with such purification their value has been correspondingly enhanced. The principle of OXLAND'S patent is that on fusing ores containing tungstates with alkaline salts, such as carbonates or sulphates of soda or potassa, the tungstic acid combines with the alkaline base, producing an alkaline tungstate, which may be dissolved out, and converted to useful purposes in calico-printing or painting, thus

returning as much if not more than the expense involved in the treatment. The tin ore, as finely dressed as possible, is mixed with as much soda ash or crude soda as will be sufficient to form an alkaline tungstate with the amount of tungstic acid which analysis shows the mineral contains. The mixture is then introduced into the bed of a reverberatory, and heated to low redness, which temperature is sufficient to induce the combination of the alkali and the metallic acid body. When the operation is finished, as observed by the color the mass assumes, and the consistency of a thick paste which it takes, it is raked out by an opening in the bed of the furnace into a receptacle beneath, whence it is taken and cast into vats filled with water, which dissolves out the tungstate of soda, leaving the other constituents of the ore untouched. By a judicious use of the water and a properly-constructed vat, the whole of the tungstate can be extracted with very few changes of water, and without diluting the solution to an inordinate degree. While this operation is progressing, the furnace is being charged with a further quantity of the mixture, which is spread out upon the sole, and left so with the furnace doors closed, till the alkali begins to melt and the mass emits a hissing sound, resulting from the expulsion of carbonic acid from the soda salt by the metallic acid. It is then slightly stirred; and when the preceding noise subsides, and the forementioned indications are observed, the roasted mass is ready for drawing. Latterly, instead of carbonate of soda, or crude soda, sulphate of soda or *salt cake* has been substituted, both on account of its cheapness compared with soda ash, and of its answering all the required purposes, in this respect, as well as the latter salt. Some skill and practical judgment are required, however, on the part of the furnaceman who has the control of the process, to insure success. The charge containing a quantity of sulphate corresponding to the tungsten in the ore, is put into the reverberatory—Fig. 603—through the workable opening, B, in the arch, and spread by the furnaceman upon the iron bed, A A, of the furnace through the working door, D. The bed is composed of two stout cast-iron plates fixed in the sides of the furnace, and supported near the centre by lines of brickwork; the space left by this arrangement between the plate and solid brickwork forming a flue for the smoke and waste gases of the fire to return under the sole, and thus assist in heating it. C is the fire which at the beginning of the operation should produce a highly carbonaceous flame, with the view of reducing the sulphate of soda to the state of protosulphide, to induce the decomposition of the tungsten and the combination of the acid. For the same purpose some small coal or charcoal is mixed with the charge, the more readily and efficiently to decompose the sulphuric acid of the soda salt. A dull red heat is maintained with all the available openings to the interior of the furnace closed, and a strong reducing flame, till the reduction of the sulphate is effected, occasionally stirring the mixture well till the phosphorescent appearance of the mass disappears. At this stage of the operation a bright oxidizing flame should be produced, to induce the further decomposition of the alkaline sulphide and the

formation of the soluble tungstate; after which it is raked out through the hitherto closed aperture, E, to the vault, F. This process has been carried out at the

Fig. 603.

Drake Wall Mine in Cornwall since 1850 with every success.

The solution of tungstate of soda obtained by the exhaustion of the fluxed ore with water, is concentrated in iron pans to the crystallizing point, and drawn off into crystallizing vessels, where it remains. In a few days the tungstate separates in beautiful crystals, and which, after slight washing and draining, are fit for market. On concentrating the mother liquors a further crop is obtained. After the ore is exhausted of its soluble salts it is transferred to the floor of the burning house, and the iron and manganese separated by washing or treatment with acids, according to the methods already detailed.

From a consideration of the several operations which ores of tin pass through from their coming to *grass*, as it is called, till they are ready for the smelter, it is supposed that fully a third or more of the quantity of tin originally in the ore is lost. Distributed as the tin must be in minute grains in the stony gangue, it is evident that the latter cannot be so thoroughly broken off from the tin as to leave it isolated, and thus in a state to separate in the several washings. Further, where the tin ore is to the whole of the matter mined as one to thirty or thirty-five, a good deal of tin must be rejected in the tailings of the first process which it has to undergo, *videlicet*, the *spalling* and picking;

and analysis of the refuse matters shows that they invariably contain quantities of tin, which loss must be entirely owing to the imperfect, or rather inadequate methods, adopted for disintegrating the ore, and the very slight difference in the low gravity of the gangue which the associated grains of tin ore must occasion, so that such ore will be entirely lost to the miner.

Modern researches show that the loss of tin in the dressing of poor ores is much greater than when richer products are operated upon, in which, however, it amounts to about twenty-five per cent. of the whole quantity. This great loss is attributed to the large amount of tailing stuff produced, and the large body of water made use of in the course of the working. Whilst the existing mode of tin dressing is practised, that loss can hardly be avoided, or at best but slightly lessened. To obtain the whole of the two to three per cent. of binoxide of tin in the tin stuff, the dressing must be based upon chemical rather than mechanical principles. Considering that the loss of tin at present sustained in dressing a hundred tons of stuff averages fully fifty to sixty pounds worth of tin, the recovery of this waste would afford a scope for a partial outlay by which to attain better and more profitable returns.

Many mining companies have of late years substituted crushing mills, such as are sometimes employed in the preparation of copper ores, for the stamping mill, and with great effect and benefit; inasmuch as the crushing mill reduces the ore to a finer state of division, and separates more of the gangue from the hard granules of tin than the stamps, and thereby renders it more easily and freely separable by virtue of its gravity, than when this breaking up is defectively performed. A mistaken notion or prejudice seems to occupy the minds of several miners, with regard to the value of crushers in their line of operations, the more especially if the stuff in which the tin ore is disseminated be indurated slate and the like; for in such cases they seem to be impressed with the idea that the crushers could not work it so well as the stampers. The evidence of many very creditable and experienced persons is directly opposed to this view; and a rational examination of the principles of working with regard to each, would undoubtedly tend to the preference of the crushers. At all events, since the tin miner places so much dependence upon the gravity of the ore as a means by which he can cheaply and expeditiously purify it from grosser and injurious matters, the primary consideration with him ought to be the reduction of the ore to the finest possible state of division. The better this is executed the more completely and expeditiously will the *whole* or chief part of the tin separate in virtue of its density, in a properly ordered system of elutriation.

ASSAYING OF TIN ORES.—Although the laws of the Stannery Court do not permit that the product of the tin mines should be sold out of Cornwall before smelting, it happens that the mining proprietors are never the smelters, and so the ores are sold to a few smelters who have the trade in their hands. These buy as cheaply as they can, and according to the declared value of the ore as ascertained by assay. Hence, as in the case of copper, the ores of tin are always submitted to

this test to find their value, and it becomes a matter of some interest to the miner, as well as the smelter, to be able to control the determinations of recognized assayers, for their own satisfaction and often protection. The operation is very simple, since the dressed ores are generally operated upon, and consequently very little of any other ingredient remains in the substance, excepting the binoxide of tin, and the silicious or other gangue matter, separable by fluxes. Still, as binoxide of tin forms permanent compounds with silicic acid at a high temperature, it is necessary to use some precautions as well in the amount of flux allotted to the assay, as in performing the reduction in a black lead crucible, or an earthen one well lined with charcoal, and at the highest temperature of the wind furnace. If sulphurous or other alterable bodies be present in the ore, these should be removed by roasting a quantity of the ore at a low red heat, and using a little ammoniacal carbonate towards the end of the operation, till nothing further is evolved. The ore should in all cases be reduced to the finest powder; and after the roasting, if the quantity of silica and stony matter be deemed in too great excess, the assay may be carefully washed in a mortar or porcelain dish, and a large quantity of the impure matters thus removed. The heavy deposit of tin ore may then be dried and assayed in the following manner. If the ore be highly dressed, two ounces of it are weighed and mixed intimately with one-third to half this weight of powdered charcoal or coke, and half an ounce of ground borax glass; the whole well ground together, and introduced into a black lead pot, or lined clay one, and this placed on the furnace, the heat of which should be maintained at its highest point for fifteen to twenty minutes. At the end of this period, and when the contents of the crucible are in tranquil fusion, the whole is briskly stirred with an iron rod, and then poured out rapidly into an ingot iron mould. When cold, the slag is detached from the button of tin by a few strokes of the hammer, and by the use of the brush; the button is then weighed. Any matters remaining attached to the walls of the crucible are scraped off and ground, then washed, and the particles of metal that may be thus separated, weighed, and the amount added to that of the principal button. Sometimes the flux is composed of equal parts of borax glass and carbonate of soda, and is found to answer very well; so also is the flux compounded of three parts carbonate of soda and one of lime. Of the former thirty to forty per cent. of the ore taken for assay is employed, and of the latter forty per cent. When ores of tin are very poor, so that they necessitate the use of large quantities of flux, very little tin can be reduced from them, on the scale of assay-making, notwithstanding a considerable amount of the metal can be obtained by the treatment of such ores on the large scale. In assaying such ores the better course would be to employ the liquid method of analysis, which will be referred to further on.

SMELTING THE ORE.—Up to the period of the reign of Charles the First, very little improvements are recorded in the smelting of tin. The remains of ancient workings discovered as existing previous to the above period, appear to indicate that the reduction

was carried on in furnaces or hearths scooped out of the ground, and in which a mixture of black tin and charcoal was placed, the necessary intensity of the heat being kept up doubtless by the blast of rude bellows, and the whole operation being similar to the metallurgic process of the travelling tinkers of a few years ago—and perhaps of the present day in Ireland—whereby cast-iron and other refractory metals were readily melted and cast into shapes, such as smoothing irons, *et cetera*. Remains of such furnaces are of frequent occurrence in Cornwall and Devon, and are called *Jew houses*. One of these smelting forges lately discovered beneath a stratum of bog, twelve feet thick, at Redmoor, contained some tin, peat which had been used as fuel, and furnace scoria, with other remains. An analysis of the scoria from other furnaces in the same locality, and apparently of a more modern date than the preceding, showed the imperfections of the methods of smelting. The following are the results which samples presenting the appearance of thin fragments of bottle glass gave:—

	Centesimally
Silica,.....	40·60
Alumina,.....	19·20
Oxide of tin,.....	22·85
Protoxide of iron,.....	7·31
Sulphide of iron,.....	9·04
Lime,.....	trace
Potassa,.....	1·00
	100·00

From the other remains found in the site of the slags, *et cetera*, from which the above was taken, it would appear that the date of working could not have been later than about the year 1630. Attempts were made in the reign of the first CHARLES to employ pit coal instead of peat and charcoal; but the results were unsatisfactory till the first few years of ANNE's reign, when improved methods of smelting ores of tin in blast furnaces, by means of fossil fuel, were patented by a Mr. LIDDELL. At this period, and when the advantage of fossil fuel above peat and charcoal began to be recognized, the invention of the reverberatory

Fig. 604.

furnace soon followed, in which forms of furnaces tin ores have hitherto, but with slight modifications, been smelted.—*Records of Mining and Metallurgy*.

Figs. 604 and 605 are a plan and section of the smelting furnace at present employed in the smelting of tin ores. In these figures, A is the fire supplied through the door, B; C is the bed of the furnace, constructed of fire-

brick, and supported by the arch, D, having a passage for cold air beneath it, and in the bridge, E, of the furnace, to prevent the overheating of the mass of brickwork in the bed. The charging door is seen at H, and G is the opening through which the charge is worked in the furnace; F is a draught-hole temporarily opened whilst the slags are being skimmed off the metallic bath, and I is the flue leading to the chimney. The ore, which generally averages from sixty to seventy-five per cent. of metal, or, as estimated by the tin assayers and smelters, twelve to fifteen parts, in twenty of ore, is mixed with twelve to eighteen per cent. of powdered anthracite coal, and twenty to twenty-five hundredweight, or a little more, of this mixture, taken for the working charge in the ordinary sized furnace; a small quantity of lime or powdered fluor spar is added in proportion to the amount of silica contained in the material. The whole is shovelled in at the charging door, and spread through this and the working door; after which both doors are closed, and the fire is urged for a period of six to eight hours, gradually increasing in intensity. At the end of this time the ore is well rabbled and mixed by the furnaceman through the hinder door, with the view of bringing the unreduced portions of ore still remaining, within the influence of the heat, and reducing flame from the fire, and the unconsumed carbon of the charge, and likewise of allowing the separated metal to collect into a bath. For a second time the doors are closed, and the interior is allowed to regain its high degree of heat, somewhat reduced during the working of the mass. After a short interval

Fig. 605.

the furnaceman throws some moist slack on the surface of the fused mass in the furnace, and then commences to draw out the top layers of scoria through the working door, to the extent of three-fourths, or thereabouts, of the entire quantity. Whilst this part of the work is being proceeded with, it is customary to open the draught-hole, F, so as to allow the gases to ascend and leave the interior of the furnace partially exposed to the examination of the furnaceman. The above quantity of scoria, if skimmed off with care, contains no metal worth further search, and therefore it is thrown away. The portions which are afterwards drawn out, however, are separated into two classes; the first and largest portion is set aside to be stamped, in order to separate the

globules, or *prills* of metal diffused through it to the amount of five per cent., or nearly so; and the second, or final skimmings from the metal in the furnace, are reserved to be melted with a succeeding charge of metal or refuse products, when not only the particles of metal are recovered, but also the tin in the state of binocide contained in it. When the metallic bath is cleaned in this way, the clay plug hitherto closing the gutter, L, leading to the cast-iron pot, K, is removed, and the tin allowed to flow into the latter. The metal rests here for some time; meanwhile a fresh charge is introduced into the furnace; after which all the apertures are closed as before, and the fire kept up, as already stated. After the metal has remained in the pot sufficiently long to permit the slag and other impurities to rise to the surface, these matters are skimmed off, and the tin is ladled out into cast-iron moulds, each capable of containing about three hundredweight.

The tin so procured always contains a certain amount of impurities, the greater when less care has been exercised in the dressing of the ore. These are generally iron, lead, and some other bodies, according to the nature of the accompanying ore, such as copper, tungsten, arsenic, and cobalt. To separate them, however, it is necessary to submit the crude tin to either of two operations—the one, a process by which the more fusible tin is sweated out at a low temperature, and called *liquation*; the other, a *boiling* or *tossing* of the metal, by which portions of it, by its extended exposure to the air in this operation, are converted into oxide; and being in this state agitated with the body of the metal, the oxygen is transferred to the more oxidizable metals, which are thrown off as a scoria, and can be removed by skimmings.

For the liquation, the smelting reverberatory above described, or one similarly constructed, may be used. The blocks of tin are loosely piled upon the hearth, and a moderate heat is applied; the excess of pure tin melts at the low heat, and flows out by the gutter to the receiver, leaving in the furnace an alloy richer in impurities, and therefore, owing to the more refractory nature of the alloyed metals, requiring a higher temperature for melting it than the purer tin. As the progress of heating crumbles and melts the blocks of tin, fresh ones are supplied till about five or six tons of metal have run out to the cast-iron receiver, wherein the second operation is conducted. This receiver is so arranged as to admit of being heated with the view of aiding in the more ready separation of the contaminating ingredients during the boiling or tossing.

The purification by boiling is analogous in principle to the *poling* practised in refining copper, though differing in detail. In the case of copper, the gases eliminated from the wood—watery vapor principally, and some carbohydrogen—serve to decompose the metallic sulphide left, eliminating the sulphur as sulphurous acid and sulphide of hydrogen; whilst in that of the purification of tin, the metal abstracts oxygen from the steam similarly generated, and the oxide of tin thus partially produced, reacts upon the particles of alloyed metals more oxidizable than itself, and eliminates them as oxide, being itself reconverted to the metallic state.

The method of procedure with tin is to have a bundle of billets of green wood mounted on a crane erected by the furnace, and overhanging the pot containing the melted metal; this bundle is forced into the fluid mass, and the result is a violent seething, caused by the eliminated gases. A scum forms in which oxide of tin is a constituent; this is skimmed off and retained to be remelted with a fresh charge, or with the scoria produced in the first reduction. The action of the wood is renewed, and the scum removed, till by a test applied to the metal it is judged sufficiently purified.

Instead of using wood, the process of *tossing* may be practised with the same effect; that is, the metal is taken up in ladles and allowed to fall from a certain height into the caldron; in this case a scum is formed, and is removed in the same way as stated till the metal is deemed pure. The time occupied in the purification averages about five hours; one hour is devoted to the liquation, three to the boiling or tossing, and one to the subsidence of the metal after it has been thoroughly cleaned by the repeated skimming. During this final hour the metal disposes itself into three qualities of tin: the purer and more fluid metal constitutes the top layer, which is carefully cast or ladled into the moulds, and set aside as grain tin; the middle, which is not so pure, is likewise removed to moulds and retained as common tin; whilst the third portion is returned to the furnace to undergo liquation a second time, to purify it from the greater part of the vitiating ingredients.

The manner of testing the quality of the metal is as follows:—The refiner takes a small ladleful of the melted metal, and having cleaned it by stirring and skimming, casts it into a stone ingot mould, and as it cools, he closely observes its appearance. If it remains bright and clear, full and rounded on the sides, until quite cold, it is sufficiently pure to be classified as grain tin; if the metal, though bright, should not remain so full and rounded at the sides, and if at the moment of solidifying a frosted crystalline appearance shoots from the centre out to the sides, the tin is accounted as second class or common tin; and in the third place, if the metal assumes a slight yellowish appearance, and the crystalline stria appear much sooner, covering the whole of the surface, it is of the third class, and must be repurified by liquation, *et cetera*. The creaking sound emitted by the ingots when bent, is likewise a test which shows the quality of the metal, for this is much greater in proportion to the purity. In tin-smelting works, one day a week is usually devoted to the purification of the crude metal from the reduction of the ore.

The matter remaining in the furnace after the liquation of the tin, is melted at a higher temperature, and run out into another pot, whence it is cast into moulds. This, with the metal washed out from the rich slags after stamping, and the skimmings of scoria, as well as those produced in the refining pot, are resmelted, and the metal which results carried through the same course of operations detailed above. Finally, there remains in the pot a bright brittle alloy, having a crystalline fracture and so surcharged with foreign

metals that it is cast aside as not worth the expense and trouble of purification.

The following is the composition of the three qualities of tin obtained by the preceding operations, according to BERTHIER's analysis:—

	Centesimally.		
	Ordinary Tin.	Common.	Bad.
Tin,.....	99.76	98.64	95.00
Copper,.....	.24	1.16	3.00
Lead,.....	—	.20	1.50
Iron,.....	trace	trace	—
Arsenic,.....	trace	trace	trace
Loss,.....	—	—	.50
	100.00	100.00	100.00

The consumption of fuel for producing one ton of tin is reckoned in the Cornish smelting works at a little more than a ton and a half, sometimes thirty-five hundredweight, and the loss of tin in the process amounts to about five per cent.

German Method.—In the tin-smelting establishments of Altenberg, *et cetera*, instead of the reverberatory, a

Fig. 606.

small blast furnace is used for the reduction of the ore. Figs. 606 and 607 are a plan and elevated section of this furnace; its height from the hearth to the throat, by which the mixture of ore and fuel is inserted, is fourteen feet. The body, A A, is constructed of large blocks of granite or of coarse-grained porphyritic syenite, and the sole or crucible is formed of a block of the same material hewn to the proper shape, with a fall to the breast of the furnace; but sometimes it is constructed of very refractory fire-bricks, lined with a mixture of charcoal and fire-clay well rammed down. A channel from the furnace leads into a basin, B, from which the slags flow down an incline, G, to the water

cistern, H, where they are cooled, and the tin by another conduit, K, flows into the vessel, C. The blast is supplied by the bellows, I I, through the tuyere opening, O. The furnace is surmounted by a dome which serves to carry off the vapors, and as a depositing

Fig. 607.

chamber for the particles of ore driven out of the furnace by the blast. The shaft, D, is turned by the cog-wheel, E, in connection with a shaft from a water-wheel or steam-engine. The small furnace, the parts of which are similar to the preceding, is employed for resmelting the slags produced from the larger furnace. The furnaces are slowly dried after their construction, and then charged with scoria and fuel, and the blast slowly set to work, so as to fuse the more vitrifiable portion, after which the heat is increased till the temperature is raised to the working intensity. The ore, mixed with the reducing agent, and other flux, when necessary, is now charged portionwise, and the smelting proceeded with. At the end of four hours the metal begins to flow. As the slags collect in the basin at the face of the furnace, they are skimmed into the water cistern, and when the metal accumulates so as to nearly fill the basin, it is allowed to flow into the outer one, C, whence it is cast into moulds of varied dimensions. Much of the same practical knowledge is required in the management of this furnace; as has been pointed out under the smelting of copper ores in the blast furnace; for the length of the nozzle formed of the slags, on the end of the tuyere affects the working, and the charge must be regulated accordingly.

It is affirmed that the tin reduced in the blast furnace is purer than that smelted in the reverberatory; but the loss of metal and the consumption of fuel is much greater; and these disadvantages have led to the abandonment of the blast furnace in England for the reduction of tin. Smelting by the use of the blast involves a loss of metal averaging fifteen per

VOL. II.

cent., and a consumption of fuel amounting to three tons of coal for every ton of metal reduced.

Tin is sent to market as *block tin*, in blocks of three to half a hundredweight, and which are cast, as stated in the foregoing, in strips two feet long, one inch wide, and half an inch thick, being so cast in moulds of white marble; and in the form of *grain tin*; the last being produced by heating large blocks of the metal to nearly its melting point, and while in this state, dropping it upon a hard body from an eminence, or striking it with a heavy hammer—in either case, the mass is shattered into long crystalline fibrous columns.

USES OF TIN.—The principal uses of tin are for the manufacture of various alloys which are largely used in the arts, such as bronze, bell-metal, solder, *et cetera*; for making *tin plates*, or rather iron plates, alloyed with the metal; and for preparing tinfoil, whilst its compounds are employed for pottery, in glazes, and colors; and in cloth-printing, as mordants of great value and importance. The reader will find the account of bronze under COPPER, Vol. I., page 534, and of solder, usually compounded of two parts of lead and one of tin. Tin-foil is manufactured similarly to lead-foil, by passing slabs of it backwards and forwards under a pair of rollers; the temperature of the metal being raised occasionally, or maintained throughout, at 212°. The production of tin plates is one of the principal, if not the principal application of tin, and as such this manufacture will be described more in detail.

MANUFACTURE OF TIN PLATES OR SHEET-TIN.—As the superior quality of tin plates depends almost entirely upon the goodness of the iron which constitutes their basis, and the care taken in its preparation, it will be necessary, from the importance of the subject, to dwell at some length upon this part of the process.

The pig-iron selected for the manufacture is generally that known as *red short*; but other varieties may be used, the iron being converted during the purification into plates, the essential qualities of which are great tenacity and toughness at ordinary temperatures. Iron from hematitic ores mixed with other pure ores of the coal measures, answers all the required ends. It has an average composition corresponding with the following samples, containing centesimally:—

	I.	II.	III.	IV.	V.	VI.	VII.
Carbon.....	3.47	3.70	2.37	3.42	4.23	3.27	—
Silicium....	1.40	1.33	0.81	1.63	0.49	1.03	1.55
Sulphur....	0.10	0.02	0.54	0.15	0.37	0.04	0.05
Phosphorus	0.60	0.12	0.26	trace.	0.36	0.38	0.18
Iron.....	94.43	94.93	96.02	94.80	94.55	95.28	—
	100.00	100.00	100.00	100.00	100.00	100.00	—

Tin plates are divided into two classes, and known by the terms *charcoal* and *coke* plates, owing, in the first place, to the nature of the fuel used in the preparation of the plates before tinning; but, more particularly at present, these names serve to distinguish the goods manufactured by entirely different methods. Charcoal tin plates were the first that were made, and they have been accounted the best. The iron for these plates is rendered tenacious and workable by the aid of a charcoal refinery through which the pig-iron, is passed; and that for the *coke* tin plates is prepared by the

G T

ordinary method of puddling and rolling, as described under the article IRON. It will, therefore, be unnecessary to revert to the latter; and so far as the mere coating of the prepared plates is concerned, the description to be given will answer for both. To convert the iron into charcoal tin plates, it is necessary to refine it in a shallow furnace called a *refinery*, the sides and bottom of which are formed of hollow, but very massive blocks of iron, through which a stream of water is kept continually flowing, to protect them from the intense heat of the melted charge. This furnace is of a rectangular shape being four feet long, two and a half wide, and one and a half deep. On one side are three tuyeres for the admission of blast; and these are sometimes round, sometimes oval, the transverse diameters of each in the latter case being 1·15 inch, and its conjugate one inch; they are placed about a foot from the bottom of, and project considerably into the furnace, inclining downwards at a sharp angle. These, like the block forming the furnace, being subjected to a powerful heat, are protected by a coil of iron pipe, twisted round them, through which pipe a stream of cold water is kept always passing. Occasionally, refiners are constructed of larger dimensions than that described, having tuyeres at both sides; these are usually called *double refiners*. A coke fire is made in the space between the *water-blocks* or hearth, and the blast turned on till the whole is thoroughly ignited; a fresh supply of fuel sufficient to fill the space to the height of three feet above the tuyeres, is then heaped on; and, after a few minutes' blowing to increase the heat, a charge of pig iron, varying according to the size of the furnace, and generally reduced for the first time, is put on; the coke is soon ignited, and the metal attains a red heat quickly, after which, the heat being still kept up with fresh supplies of fuel, the metal gradually sinks, and as it comes into contact with the blast, it melts and drops to the bottom of the hearth. The downward direction of the tuyeres causes the stream of air to impinge on the highly-heated liquid iron, and thereby renders the temperature of the latter intense, owing to a portion of the metal being oxidized, as well as the silicium, sulphur, *et cetera*. All these products of oxidation are thrown up to the surface, and form a considerable amount of scoria or cinder that considerably aids in the depuration of the metal. Generally, in an hour and a half after charging, the furnace is fit for tapping; the metal is run out into iron moulds prepared for it, and which are protected against melting by a stream of cold water that flows beneath them. These moulds are sometimes flat, in which case the metal is called *plate metal*. In South Wales, however, it is more usual to run the liquid iron into moulds, consisting of three longitudinal grooves or channels,

having raised dams or *stops* at the distance of every five feet, to facilitate the breaking of the metal. As it runs out of the refinery, it is covered by minute, intensely brilliant, and very numerous coruscations arising from the combustion of a portion of the fluid; these coruscations are accompanied by a brown smoke—a phenomenon also of the BESSEMER process. As the metal runs out, the slag or cinder, which is likewise highly heated, flows after it, forming a layer on the surface of the moulds, and thus prevents further combustion of the iron. Cold water is now thrown on the whole, when the cinder at once froths up and solidifies on the surface, causing it to assume a spongy appearance that distinguishes it from all other kinds of slag formed in the several processes for refining iron. The first charge worked in the refiner is less than the following ones; but the normal weight, about twenty-two hundred-weight, is attained after the third. The number of charges worked every twenty-four hours is eleven or twelve; and the weight of refined metal produced in a week of six days and five nights averages sixty tons, for which about seventy-two tons of pig are required. The produce varies, however, according to the skill of the refiner, the quality of the material used, and the nature of the required product.

Good refined metal has a bright silvery-white fracture, and a radiated structure, the rays springing and diverging from the lower side; it emits a clear metallic sound when struck, is very brittle, with its upper surface indented into a kind of honey-combed structure, the depth of the indentations being dependent on the length of time that the iron has been subjected to the blast. About half an inch deep of honey-comb is considered to indicate the state of refinement best suited for the making of tin plates. It is somewhat curious that, as the refined metal graduates into steel, the honey-comb leaves the face or upper side, and tends to the centre of the horizontally-cast ingot.

The effect of the refining, as before stated, is the removal of the silicium, and of a portion of the sulphur and phosphorus contained in the crude material. The silicium is converted by oxidation into silicic acid, which combines with a portion of the iron oxidized, and forms a fusible slag or cinder on the surface of the metallic bath. The sulphur is converted into sulphurous acid gas, and passes off as such, and the phosphorus into phosphoric acid, which is retained in combination with the oxide of iron in the slag. Very little of the carbon, contrary though it be to the preconceived opinion of iron-masters, is removed during the preceding course of refining, as is sufficiently proved by analysis, and will be evident from an examination of the annexed table showing the composition of different specimens of refined iron:—

	I.	II.	III.	IV.	V.
Carbon.....	3·070	3·250	2·000	3·200	—
Silicium.....	·630	·500	·540	·550	0·32
Sulphur.....	·157	·575	1·250	0·870	0·18
Phosphorus.....	·734	·835	·985	·920	·09
Manganese.....	trace	—	·056	trace	·24
Insoluble residue.....	·530	·050	—	—	—
Iron.....	95·140	96·300	94·255	95·000	—
	100·261	101·510	99·046	100·540	—

Although the above samples were not made from the cast-irons, the analyses of which have been previously given, yet they serve to prove what has been just stated regarding the chemical changes that take place in the fire. By comparing the results of the two series of analyses, it will be found that only one-seventh of the carbon is separated at the same time that one-half of the silicium is removed. On the other hand the sulphur and phosphorus are in larger quantities in the samples of refined than in the crude metal, showing at least that very little if any of these elements are separated, or else that the crude material submitted to the process was of very bad quality. It appears, however, that fully one-third of the content of phosphorus and somewhat more than this amount of the sulphur, with nearly the entire silicium in the pig, are thrown off, the carbon suffering only a slight diminution.

The following analysis shows the nature of the refining cinder thrown off during the operation:—

Silica	23.76
Protoxide of iron	61.28
Oxide of manganese	3.58
Alumina	7.30
Lime	2.41
Magnesia	0.76
Sulphur	0.46
Loss	0.45
	<hr/> 100.00

Besides the foregoing method of refining, two others, long followed to some extent, are known—the first is a modification of BESSEMER'S process, and the second is one patented by Mr. PARRY of the Ebbe Vale Iron Works. In the first, the action of the blast is stopped when the melted iron has passed to the state of refined metal; but as the iron prepared in this way has never been used in the manufacture of tin plates, it will be needless to prolong the description. The metal purified from common Welsh pig contains centesimally—

Sulphur	1.040
Phosphorus	1.128
Silicium	trace

PARRY'S process differs considerably from those referred to. According to it the melted pig-iron is run at once from the blast into a reverberatory furnace very similar to that used in puddling. On each side of this are three or four small tuyeres pointing downwards to the hearth, through which superheated steam is forced at high pressure; they are so arranged that the current will cause a gyration of the surface of the metal, and thereby expose fresh surfaces of it continually to the blast. The action produced is similar to that effected in the ordinary refinery—the oxygen of the steam, together with that passing over the grate, causes the necessary oxidation, and, therefore, the formation of cinder as before. It should be observed that in this process a considerable quantity of rich cinder, such as hammer slags, mill-scales, *et cetera*, is added to the melted metal in the refinery, and the result of the union is that much of the iron in those cinders is reduced and converted into refined metal, so that in most cases the product equals the amount of metal introduced from the melting furnace. This

result is brought about by the carbon in the molten mass acting upon the rich slag, and reducing the iron in it to the metallic state simultaneously with its own consequent conversion into carbonic oxide, in which form it escapes; hence the cinder produced, though abundant, contains less iron than that formed under ordinary circumstances, namely, only thirty per cent. The hydrogen, likewise, has an important effect; it acts upon the sulphur and phosphorus of the metal, and converts these into sulphide and phosphide of hydrogen, which, like the carbonic oxide just mentioned, escape. The metal is thus rendered much purer, and well adapted for the manufacture of tin plates.

The next operation is the refining in the charcoal fire, in a furnace similar to the old blooming fire used in this country previous to the introduction of the puddling process. It consists of a shallow hearth eighteen inches deep, twenty-eight by thirty-two inches at the upper part, and twenty by twenty-one inches at the lower. On one side is placed a Δ -shaped tuyere protected, like the others spoken of, seven or eight inches from the bottom. The tuyere side and that opposite to it are occasionally constructed of *water blocks*, but generally of dry iron plates. Charcoal is the fuel used, and, in recently-constructed works, the products of combustion pass through a chamber at the back of the fire, and there raise the charge of metal to a red heat previous to its introduction into the fire. The refined metal being thus heated, it is drawn down into the fire, the whole of the hearth of which has been previously filled with charcoal, so as to completely cover the tuyere; more fuel is then added, and the blast turned on. In twelve to fifteen minutes the metal begins to melt, and at the end of forty-five minutes it is completely molten and lies on the bottom just under the blast. The workman now proceeds with a bar to break it up and raise it into more immediate contact with the blast, exposing it by this operation on all sides. A small quantity of cinder is thus formed, after which it is tapped off and another charge of heated metal let down and treated in the same way till the whole coheres into one mass. This occurs about an hour after charging. At this period it is usual in most tin works to add a bundle of shavings, cut from the edges of the *black plate* presently to be described. This new addition is very quickly blended with the previously formed *loops* of iron; so that in about ten minutes after adding it, the whole will be in one mass at the bottom of, and nearly filling, the hearth. During this part of the work very little fuel is required, merely sufficient to cover the iron. It is now taken out of the fire and freed from scurf and cinder as much as possible, all the pieces thus separated and the scales from the *helve* being taken back to the fire for the next charge. The loop is first hammered into a roughly cylindrical bloom and then into a flat irregular shape of about two inches thick. In this plate are cut deep grooves parallel with one another, and six inches apart. It is then thrown into cold water to cool, and broken into the rectangular pieces previously roughly indicated by the parallel grooves or notches. The charge of refined metal taken in this operation is about two hundred and seventy pounds, and the loss is such that to make one ton of

charcoal-refined, or stamped iron, as it is sometimes called, requires twenty-two hundreds of refined metal and about eight bags—equal to one hundred and twenty cubic feet—of charcoal. The number of charges worked off in the twenty-four hours averages eighteen.

The effect of this process is to continue, and, in a

great measure to complete, the purification begun in the previously described process, the result being, in fact, crude wrought-iron. The fresh fracture presents very large, bright, and flattish crystals, of a silvery color; and its fitness for the subsequent processes is mainly judged of by its appearance, and by the manner

Fig. 608.

Fig. 609

in which it breaks under the hammer. In fact this is almost the most important operation in the whole series which constitute in the aggregate the manufacture of tin plates; and if it be not properly conducted all subsequent treatment results in loss and vexation. The chemical reactions that are effected are a continuation of the carbon in the iron, and the separation of the sulphur and phosphorus, with other impurities, by the same agency. The similarity between the two methods now treated of and the BESSEMER process must be apparent to every one; the only difference being the presence of carbon in both, the plans described, to prevent the excessive oxidation and loss resulting from the patented method of BESSEMER.

In some works it is usual to run the fluid metal direct to the charcoal fire, and this practice certainly economizes fuel, as all the caloric absorbed in raising the refined metal from its cold state to the melting point must be saved. When this is the case, the refinery is made very much smaller than that before mentioned, and is charged with only six hundredweight of pig, which, when refined, supplies two charcoal fires. This kind of furnace is often called a *running out* or *dandy fire*—Figs. 608 and 609, the former a plan and the latter a vertical section on the line A B of the plan—and is now very generally used. Instead of using charcoal in these fires, it is customary in some localities to use a very light, spongy coke, and this difference gave rise to the terms *coke* and *charcoal* plates, though at present the former name is applied to puddled iron. Coke of this nature has received great attention recently; and there can scarcely be a

doubt of the fact that if this fuel is carefully manufactured from a proper and pure coal, and finished by the action of steam while hot, according to a process lately patented by Mr. R. S. ROPER, it forms as good a fuel as charcoal; and that tin plates made in this way are not to be distinguished in appearance or quality from the charcoal plates.

The charcoal iron next undergoes a reheating and welding process. One of the rough irregularly oblong pieces, weighing about thirty pounds, is laid on a flat plate of iron with a long handle, called the *portal* or *staff*, and placed in the *hollow fire*—shown in elevation in Figs. 610 and 611—where it is raised to a soft welding heat previous to reducing it to blooms. Fine sand is thrown on the surface of the metal from time to time, to remove the oxide or *scale* formed on it by the action of the heat and the free oxygen entering the fire, which scale, if left on it, would interfere with the proper welding. Afterwards it is carried to the hammer and beaten into a bloom, as stated above, and welded to the portal; this is again returned to the hollow fire, three other pieces of the charcoal iron being previously placed upon it, and after its temperature is raised as before, again worked into a bloom six inches wide and two thick under the hammer. This is cut nearly in the middle, and the parts doubled up on one another—reheated—rehammered into a bloom six inches by four—then taken to the hollow fire to be reheated—cut off from the portal—and finally passed several times through a series of grooves in a pair of rollers till it is reduced to a bar or slab six inches wide and half an inch thick. These dimensions,

however, vary slightly particularly the thickness, according to the size and gauge of the plates afterwards to be rolled from them.

The *hollow fire* alluded to is one of the earliest applications of the gas flame to metallurgical purposes, having been in use upwards of seventy years, previous to which an earlier form, was used, and is still employed in the charcoal forges of North Lancashire; in this early form the iron was surrounded by a dome

Fig. 610.

Fig 611.

of ignited fuel, the flame from the combustion of which produced the necessary heat. In the present modification, the furnace is of bricks, and in three divisions—at one end is a space containing ignited coke, into which a continued blast of air is blown by two tuyeres; the flame thus produced passes into the middle position, where the iron to be heated is placed; and the third or middle-end division is intended for the partial heating of said iron by the waste heat, preparatory to its being introduced to the middle division.

The operation just described is a most wasteful one, involving a loss of three or four hundredweight of iron per ton of bars made; and this is the more striking as the material operated on is wrought-iron. It is owing chiefly to the numerous heatings to which the metal is submitted, and the large volumes of oxygen that enter the furnace through its numerous openings, and possibly also the excess of blast blown into the coke. The latter cause of loss might be avoided by care on the part of the workmen; but it is to be feared that the waste can be but slightly diminished while so many

apertures for the entrance of air are allowed to exist. To remedy the evil many experiments have been made to avoid this process altogether, but hitherto without leading to the adoption of any advantageous plan. Mr. WILLIAM DANIEL patented a mode of dispensing with the operation, but it is only partially carried out, though it was in a great measure successful. He directs to put the lump from the charcoal refinery under the hammer, where it is *nobbed* or hammered into a roughly cylindrical bloom, then passed through the rolls and reduced to a bar six inches square and about two feet and a half long. This bar is then either cut or sawn into pieces six inches long, and rolled endwise to give a bar six inches wide, two and a half thick, and twelve long; afterwards this billet is heated in a small balling furnace, and rolled down to a bar a quarter of an inch thick, eleven wide, and about six feet long. This is at once taken to the tin plate mill and made into plates.

It is necessary to revert here to the *coke tin plates*, which name, as already stated, was originally applied to them in consequence of the kind of fuel used in the second refining operation. At present it means those produced from puddled iron rolled into bars similar to those described in the preceding, and called *tin-plate bars* or *tin bars*. In all the subsequent processes the same *modus operandi* is followed, whether the tin bars be made from the puddled or from the hollow fire iron—charcoal tin bars; therefore the following description of the process to which the bars are subjected, previous to, and up to their conversion into tin plates, applies equally to both kinds.

The bars are taken to the shears, where they are cut to proper lengths in accordance with the size of plates to be made—thus for No. 1 c plate, which is $13\frac{1}{2} \times 18$

—see table, page 1071, the length of piece will be fifteen inches, the exact dimensions of it being $15 \times 6 \times \frac{3}{8}$ inches. These short pieces are then placed in packs in a reheating furnace, having a very slow draught, and there raised to a dull red heat; they are next passed singly breadthwise several times through a pair of narrow flat rolls; reheated, and then drawn out across the original fibre to a length of five feet and a half. Such plates are then doubled down, and the ragged ends produced in the rolling shaved off. After this they are returned to the furnace and heated to redness, passed through a pair of rollers similar to the last, but more carefully turned to give them a very smooth surface, and there rolled till each is drawn out to five feet—this virtually being two plates five feet long united at one end. The combined plates are again doubled, the waste end sheared off, returned to the fire, and when heated repressed under the rolls till they are extended to about forty-three inches, the entire forming four plates. The operation of doubling, heating, and rolling, is continued sometimes till the original plate is reduced to eight and even sixteen

plates, all passing under the rollers as one. It is to be observed, that great care is required to prevent the plates from being welded either by a too high heat, or from a neglect of partially separating them from time to time, by the rollers. In this way the original piece of bar is rolled into four sheets, each forty-three inches long by fifteen wide. The plate of four, eight, sixteen, or thirty-two thicknesses, or sheets, is then taken, unopened, to a pair of shears, which cut off the two ragged longitudinal edges at one stroke, and at such distances as to determine the length of the tin plates; they are then cut across by the same machine at distances equal to the intended breadth of the same; and thus are obtained four, eight, sixteen, or thirty-two plates in each division of the proper dimensions, still so closely pressed as apparently to be but one. They are next separated, and all the defective ones picked out; such, for instance, as contain streaks of dirt pressed into them, those welded together, and the like, and the choice ones, called in this state *black* plates, are taken to the *pickling* room. Here they are immersed in a bath of warm dilute oil of vitriol during fifteen or twenty minutes, to remove the scale of oxide

on them. The acid leaves them with a clean dullish-grey metallic surface; and to assist the action of the acid in this respect the plates are rubbed with sand and water, and afterwards washed, when they are ready to be sent to the *annealing* house.

It will be readily understood that, after the repeated rollings and the immense strain the plates have been subjected to, they are at this stage very brittle; and therefore, if turned in this state, they would not bear to be hammered into the multitudinous and complex shapes required in commerce. To remove this defect, the process of annealing is had recourse to, and the work is conducted thus:—The plates are placed to the number of about eighteen hundred—for common sizes—in piles, within a cast-iron box about two feet square, the lid carefully luted on to prevent air entering, and then placed with several similarly filled ones in a stove constructed very much in the shape of a reverberatory furnace, but considerably larger, and having its bed on a level with the ground. The fire-bridge being tolerably high, the flame from the grate rolls slowly over the boxes, and raises them gradually to a cherry-red heat, at which temperature they are main-

Fig. 612.

tained during twelve hours, and then withdrawn. When quite cold, the covers are taken off, the plates taken out, carefully examined, and sorted. If the heat has been too high, some of the plates will be found adhering to one another; if too mild, they will not be much improved by the operation, and if air should have entered, they will be either partially or completely converted into scale or oxide of iron. After being subjected to this process, the plates will have a deep plum-color bloom on their surfaces, due to a very thin film or coating of oxide that has formed upon them. They are now passed three times through a pair of rolls similar in form to those previously described, but with which great pains have been taken, to make their surface hard, smooth, and brilliantly polished. Then rolls are placed in close proximity, so that the plates passing between them are subjected to a very great pressure, but not sufficient to enlarge them. After having been thus *cold rolled*, as it is termed, the plates are extremely smooth, and possessed of a lustrous and dappled appearance, still owing to

the thin oxidation. One effect of this rolling is to make the plates brittle once more, and therefore to necessitate a second annealing, which is performed in the same way as the preceding; but the heat is milder, and the time reduced to five or six hours. Another sorting follows, when the good plates are sent to the *tin house*, and the defective ones returned with the shearings of the *black* plates to the *charcoal fire*.

In the tin house the plates are again *pickled* in a warm but more dilute bath of oil of vitriol than that already used, during ten minutes, then removed and well rubbed with sand and water, to detach all dirt and scale. They should now have a smooth, perfectly clean, greyish metallic surface, in which state they can be kept in cold water without injury for some time, and are ready for the *tinning*.

TINNING.—The apparatus or *stow*—Fig. 612—for this process consists of a series of baths set side by side, for the convenience of the workmen, each bath having a fire beneath it, to keep the materials they severally contain in a fluid state. These baths

or pots are six in number—namely, 1, the tinman's pot; 2, the tin-pot; 3, the washing or dipping pot; 4, the grease-pot; 5, the cold-pot; and 6, the list-pot. The tinman's pot is full of melted grease, and into this the plates are immersed and left till all moisture upon them is evaporated, and they become completely covered with the grease. It is about two feet long, fifteen inches wide, and twenty inches deep. From the tinman's pot the plates are removed to the tin-pot, and plunged into the bath of melted tin, protected with a layer of grease which it contains, and remain in it for about twenty minutes. This pot has a capacity of $22 \times 18 \times 16$ inches. In the first dipping the alloy is imperfect, and the surface not uniformly coated, consequently the plates are removed to the dipping or wash pot, which is divided into two compartments. The first immersion takes place in the larger division, which contains molten tin covered with grease like the last, and here the plate is left sufficiently long to make the alloy complete, and to separate any superfluous tin which might have adhered to the surface. The workman then takes out each plate separately to a table between the wash-pot and the grease-pot, and wipes it on each side with a brush of hemp to remove any excess of tin; to obliterate the marks of the brush, he dips it quickly into the second compartment of the wash-pot, and then at once into the grease-pot. This second compartment of the wash-pot always contains the purest tin; and as it becomes alloyed with iron, it is removed to the first compartment of the same, and thence to the tin-pot. The grease-pot is filled with melted grease; and great care is necessary to maintain it at the proper temperature. Its purposes are to allow any superfluous tin to run off, and especially to prevent the alloy on the surface of the plate cooling more rapidly than the iron. If this were neglected, its surface would be cracked. After ten minutes' immersion in the grease-pot the plate is removed to the cold-pot, which is filled with tallow heated to a comparatively low temperature. The pots 4 and 5 serve the purpose of annealing the plates, and of cooling them down

to a low temperature. The last one in the series is the list-pot, and is a small cast-iron bath kept at a sufficiently high temperature, its bottom covered with tin to the depth of a quarter of an inch. In this the edges of the plates are dipped and left in till the wire of tin, which usually forms on them in the course of the foregoing processes, melts, and is removed by a quick blow on the plate with a stick.

The articles are now tin plates; but before they are sent to market, they undergo some further treatment. Firstly, they are carefully rubbed with bran to clean them from grease and dirt; secondly, they receive another rubbing with a pad of sheep-skin, retaining its wool; and thirdly, they are sent to the sorter, whose duty it is to pick out defective plates, and to arrange the good ones in piles according to their size and quality. They are finally packed in boxes, which are branded on the outside with the marks indicating the size and quality of the plates, and sent to market.

Quality of Tin Plates.—The tests for tin plates are ductility, strength, and color; and to possess these, the iron used must be of the best quality, and all the process be conducted with care and skill. The following conditions are inserted in some specifications, and will serve to indicate the strength and ductility of first-class tin plates:—

1st, They must bear cutting into strips of a width equal to ten times the thickness of the plate, both with and across the fibre, without splitting; the strips must bear, while hot, being bent upon a mould to a sweep equal to four times the width of the strip.

2nd, While cold, the plates must bear bending in a heading machine, in such a manner as to form a cylinder, the diameter of which shall at most be equal to sixty times the thickness of the plate. In these tests, the plate must show neither flaw nor crack of any kind.

The following table exhibits the usual brands and their value in dimensions of plate, number, and weight per box, and may be found useful for reference:—

TABLE OF MARKS, WEIGHTS, AND DIMENSIONS OF TIN PLATES.

The Editor thankfully acknowledges his obligations to his late talented pupil, Mr. R. S. ROPER, for his assistance in preparing the preceding remarks on tin plates.

ULTRAMARINE.—*Outremer*, French; *Lazurstein*, German.—This is one of the most beautiful pigments known, and its artificial production is justly viewed as belonging to the greatest triumphs of modern chemistry. It is obtained by isolating the coloring matter of lapis-lazuli, outremer, or lazurstein, mostly brought from China, Thibet, and the shores of Lake Baikal. It is a mineral of indeterminate composition, as will be seen from the annexed analyses—

	Gmelin.		Dann.
Silicic acid,	49·00	45·50
Sulphuric acid,	2·00	5·90
Alumina,	11·00	31·80
Soda,	8·00	9·10
Lime,	16·00	3·50
Magnesia,	2·00	—
Sesquioxide of iron,	4·00	0·80
Sulphur,	trace	—
Water,	trace	—
Chlorine,	—	0·40
Loss,	8·00	2·00
	100·00	100·00

Lazulite often contains scales of mica and iron pyrites. It is found in masses, more or less pure, generally in small volume, fragile, but capable of scratching glass, of granular texture, imperfectly laminated, and almost transparent at its edges. It crystallizes in dodecahedrons, with rhombic faces, but the crystals are rare—specific gravity, 2·50 to 2·96. The hue, which occurs in isolated places, merges from celestial to pure blue and indigo purple. It is usually disseminated in a rock, which contains many other laminated substances, among which is a fine white lazulite. In the *Musée Mineralogique* at Paris are two fine specimens of lazulite, in which is seen the transition from the azure to the white. TOMLINSON remarks that the iron pyrites sometimes propagated in lazulite, is of a bright yellow hue, helping to relieve the lustre of the blue, and they have often been mistaken for pellets of gold; in fact, the cause of its intense blue color was long a matter of controversy. No traces could be detected of cobalt, copper, or any other element or compound known to impart an azure tint. The existence of an unknown protoxide of aluminium— AlO —was even assumed as a means of solving the difficulty; and not until ultramarine had been prepared artificially, and the synthetic proof had thus been superadded to the analytical, was it admitted that a blue tint could be produced by the union of three colorless bodies—*alumina, sulphur, and soda*.

CLÉMENT and DÉSORMES published an analysis of this substance in 1806; they admit, of course, the great difficulty experienced in analyzing ultramarine. They regarded it to have the following composition, which is in many respects similar to the results obtained by WILKENS, and subsequently given—

	Centesimally.
Silica,	35·80
Alumina,	34·80
Soda,	43·20
Sulphur,	3·10
Carbonate of lime,	3·10
	100·00

The great cost of ultramarine, and the unparalleled effects which it produces in painting, rendered it most

desirable to produce this compound artificially. Chemists were for some time baffled by the discordant results each obtained, and were thereby unable to distinguish which of the ingredients of ultramarine were essential, and which accidental or superfluous.

The first step, says TOMLINSON, towards the production of this pigment artificially was in 1814. VAUQUELIN, in visiting the plate-glass works at St. Gobain, was informed by the director of the sulphuric acid and soda department of the establishment, that, in taking down the soda furnaces a blue mass was found when *grés*—gritstone—was employed in the formation of the sole, but there was no such deposit when the sole was of brick. The Editor has often remarked in black-ash furnaces the production of ultramarine; in fact, all recent analyses of this substance give about one per cent. of this blue pigment. VAUQUELIN took some of the compound, reduced it to powder, and, washing it, found it was decolored by the mineral acids, with the disengagement of sulphide of hydrogen; that it was not attacked by boiling alkaline solutions, nor destroyed at a red heat. This chemist further states, that though the composition of this artificial product is unlike that of lapis-lazuli, yet he is not without a hope that the circumstance may lead to the production of ultramarine artificially. This observation, and the suggestion founded upon it, appears to have been forgotten for nearly fourteen years. To GMELIN of Tübingen the honor of the discovery of artificial ultramarine is generally said to be due; but, as TOMLINSON remarks, if the question of priority were raised, then it must be claimed by the *Société d'Encouragement* of Paris, who offered a prize of six thousand francs for the manufacture of ultramarine. GUIMET obtained the prize in 1828, on which occasion he communicated his recipe confidentially to GAY-LUSSAC.

To prepare the pigment lapis-lazuli, freed from all mechanical impurities, is gently ignited, slaked in water, and reduced to an extremely fine powder. This is now incorporated with a melted paste called *pastelle*, consisting of linseed oil, wax, and resin, and kneaded under cold water. Ultramarine gradually deposits in the vessel as a dark-blue powder, which grows brighter by degrees, whilst the impurities remain entangled in the *pastelle*.

The color thus obtained is of necessity very expensive, from the rarity of the material, and from the tedious and wasteful mode of producing it.

The preparation of artificial ultramarine has undergone many modifications since the experiments of GMELIN. BRUNNER mixes seventy parts of silica, two hundred and forty of burnt alum, forty-eight of charcoal powder, one hundred and forty-four of flowers of sulphur, and two hundred and forty of anhydrous carbonate of soda, all reduced to an impalpable powder; puts the mixture in a Hessian crucible, and lutes down the cover. The crucible is heated to moderate redness, and kept steadily at that temperature for an hour and a half, and then suffered to cool. If the operation has succeeded, the mass has a loose, half-fused appearance, and a greenish or reddish-yellow hue. If solid, fused, and brownish, the heat has been too high. The mass is taken out of the crucible, and washed till the liquid has no longer a sulphurous taste. The residue, a dark

greenish-blue powder, is filtered, dried, mixed with its own weight of sulphur, and one and a half times its weight of anhydrous carbonate of soda, and heated as before. The residue is boiled with water for some time, filtered, and washed till the liquid no longer blackens carbonate of lead. The dried powder is sifted, and submitted to the following final process:—A plate of cast-iron is covered to about the depth of a line with pure sulphur, upon which the compound is sifted to about an equal depth. The plate is then cautiously heated till the sulphur takes fire. The residue is removed from the plate, again pulverized, and resubmitted to the same treatment with sulphur, until the color is found satisfactory.

PRUCKNER adopts a somewhat modified process. Sulphide of sodium is prepared by igniting sulphate of soda with charcoal powder. This is dissolved in water, some free sulphur is added, the liquid is concentrated, mixed with one half per cent. of sulphate of iron and twenty-five per cent. of a well-tempered clay—the purer and whiter the better—the mixture evaporated to dryness, the residue powdered, and ignited for an hour in a cupelling furnace; when cold, it is extracted with water, the residue dried, powdered, and once more heated in a muffle, when the required tint appears.

A still further simplification is to ignite sulphate of soda with charcoal powder and clay in a crucible, with slight access of air.

TREMON's recipe for this pigment is the following:—One thousand and seventy-five parts of crystallized carbonate of soda are fused in their own water of crystallization, and the fused mass mixed by stirring, first with five parts of red sulphide of arsenic, then with a quantity of hydrate of alumina, prepared from alum by precipitation with carbonate of soda, and containing seven parts of anhydrous alumina, and lastly, with a mixture of one hundred parts of sifted clay, and two hundred and twenty-one parts of flowers of sulphur. The mass, after being intimately mixed and evaporated to dryness, is introduced into a crucible provided with a good cover, and gently heated at first, in order to expel the remaining traces of moisture, the temperature being afterwards raised to full redness. The mass should cake together without fusing. If the materials have not been properly mixed, the whole will exhibit white spots; and if it has been fused, it is studded with brown ones. After cooling it is roasted, in order to expel the greater portion of the sulphur, then reduced to powder, and washed slightly on a filter with cold water. The bluish-green powder thus obtained is again roasted for an hour or two, with occasional stirring, in covered basins, at a temperature never exceeding low redness. According to ELSNER, a very small quantity of iron, such as is usually contained in the ingredients, is *essential to the production of the hue*, but excess is injurious. A mixture of one part of clay, perfectly free from iron, with one part of sulphur and two parts of anhydrous carbonate of soda, yields a yellowish mass when ignited; but if a trace of sulphate of iron is added to the mixture, a mass is obtained which is black, green, or blue, according to the degree of heat to which it has been subjected. When potassa is used instead of soda, GMELIN states the blue tint is not obtained.

VOL II.

Before the analysis by MARGRAF, the color of ultramarine had been attributed to the presence of copper, but this chemist only found sulphuric acid, lime, and iron; others suspected, naturally enough, the presence of cobalt; others again, hydrofluoric acid. KLAPROTH's results indicated the following:—

Carbonate of lime,	28.00
Sulphate of lime,	6.50
Alumina,	14.50
Silica,	46.00
Sesquioxide of iron,	3.00
Water,	2.00
	100.00

GUYTON thought that the coloring matter was a blue sulphide of iron.

Pure ultramarine, according to WILKENS, has the composition—

It should contain, therefore, theoretically—

	Per cent.
Silica,	38.75
Alumina,	26.37
Sulphur,	13.68
Soda,	21.20
	100.00

an assumption which agrees pretty closely with the actual analysis of the purest samples. A variety of substances, such as iron, lime, potassa, magnesia, sulphuric acid, and chlorine, may be present as impurities, and were, in part at least, purposely added by the earlier manufacturers; but they are found to be perfectly unnecessary. The coloring matter appears to consist of hyposulphite of soda and sulphide of sodium. If the firing be conducted in porous crucibles, the coloration of the mass is generally unequal.

GREEN ULTRAMARINE.—Ordinary ultramarine, on ignition with saltpetre, assumes a green color. Green portions, more or less in quantity, are frequently formed in the crucibles, especially on the first ignition. On repeated heating it passes into a blue tint. Artificial ultramarine is, however, very rarely entirely freed from all traces of the green modification, and hence it is, for the most part, less beautiful than the natural variety.

Ultramarine is readily decomposed by acids, with evolution of sulphide of hydrogen, and total destruction of the color. At a high temperature this effect is even produced by silica, whence the unfitness of ultramarine for painting on glass and porcelain. Solutions of potassa and soda have no decomposing action, even at a boiling temperature. By a prolonged red heat ultramarine is rendered perfectly white, and then no longer evolves sulphide of hydrogen on the addition of an acid.

Tests.—Purchasers frequently judge of the comparative value of samples of ultramarine by mere inspection—a most fallacious method. The eye may indeed decide on the purity of the blue, but it can give very little notion of its depth. In other words, it is impossible to determine, by mere inspection, how far a sample has been let down with some colorless substance. It is better to take equal weights of the respective samples under examination, and to grind up each with

6 U

ten to twenty times its weight of gypsum. When thus let down, a difference in the depth of color becomes perceptible.

BERNHEIM prepares a normal solution by mixing one ounce of concentrated sulphuric acid with twenty grains of water; equal weights—fifty to one hundred grains—if the various samples to be examined are next taken, and each placed in a separate glass. The normal liquor is now added from a graduated burette until the blue color is converted into a reddish one, and no blue particles are perceptible. The quantity of sulphuric acid consumed in each case shows the relative value of the sample. If cobalt is present, the blue color of the sample cannot be completely destroyed by the acid.

Uses.—Ultramarine is employed as a pigment by artists and decorators. Under certain circumstances, however, it gradually loses its color if ground with oil. It is also used in printing cotton and woollen goods, being fixed to the fibre either by solutions of albumen and casein, or by shell-lac varnishes. It is abundantly employed as a *powder-blue*, in getting up white cotton and linen goods. For this purpose it is ground up with soda-ash, chalk, gypsum, or any other cheap white matter, and sold sometimes under its own name, but more frequently as superfine Saxon smalts. This fraud is much in vogue in a sea-port town on the Eastern coast of England notorious for its manufacture of inferior and spurious colors. The detection is not difficult, since hydrochloric acid at once destroys the color of ultramarine, whilst it is without action upon genuine smalts.

VARNISH.—*Vernis*, French; *Firniss*, German.—In the commonest acceptation of the term, a varnish consists of a resin of some description dissolved in a fluid more or less volatile, which, on evaporation, leaves the resin in the form of a lustrous film. It is generally applied by means of a brush in successive coats, and is laid on in the direction of the fibres of the wood. The most desirable feature of a good varnish is durability, dependent upon the quality of the resin and its solvent.

The principal substances employed in making varnishes are the following:—

SOLVENTS.

Oil of nuts—alcohol.
Oil of linseed—ether.
Oil of turpentine—wood-spirit, pyroxilic alcohol, or hydrated oxide of methyle.
Oil of rosemary—methylated spirit.

SOLIDS.

Amber,	Colophony,	Elemi,
Anime,	Copal,	Lac,
Benzoin,	Damara,	Mastic,
	Sandarac.	

COLORS.

Aloes,	Dragon's blood,	Red saunders,
Anatto,	Gamboge,	Saffron,
Cochineal,	Indigo,	Turmeric.

The spirituous varnishes dry most rapidly; this advantage is, however, partly counterbalanced by their aptitude to crack and to peel off. This defect is partially remedied in the turpentine varnishes which dry more slowly. But in those called *oil-varnishes*, this defect is alone entirely obviated: in these a small quan-

tity of a drying oil is added to the solution of the resin in rectified spirit of turpentine; and although they take a longer time to dry, they are all the more durable.

Before treating of the various varnishes, a description will be given of the chief resins before mentioned, as being employed in the manufacture:—

Amber is most distinguished for durability. It is usually of some shade of yellow, transparent, hard, and moderately tough. Heated in air it fuses at about 549°; it burns with a clear flame, emitting a pleasant odor. When pounded, absolute alcohol extracts succinic acid and resin; the latter to the extent of about one-eighth of the weight of the amber. In fact, amber is a mixture of several resins. It resists the action of solvents so greatly, that it requires to be fused and kept in a state of fusion—for oxidation—at a somewhat high temperature before it is fitted for making amber-varnish. The costliness of amber, as well as the length of time it takes to dry, are the chief objections to it.

Anime is imported from the East Indies. The large, transparent, pale-yellow pieces, with vitreous fracture, are best suited for varnish. Inferior qualities are employed for manufacturing gold-size or japan-black. Although superior to amber in its capacity for drying, and equal in hardness, varnish made from anime deepens in color on exposure to air, and is very liable to crack. It is, however, much used for mixing with copal varnish.

Benzoin is a gum-resin but little used in varnishes on account of its costliness. The finer sorts are brittle, pulverulent, with conchoidal fracture; they fuse at a gentle heat.

Colophony is synonymous with arcanson and rosin. When the resinous juice of *Pinus sylvestris* and other varieties is distilled, colophony remains in the retort. Its dark color is due to the action of the fire. Dissolved in linseed oil or in turpentine by the aid of heat, colophony forms a brilliant, hard, but brittle varnish.

Copal is a gum-resin of immense importance to the varnish-maker. It consists of several minor resins of different degrees of solubility. In durability it is only second to amber; when made into varnish, the better sorts become lighter in color by exposure to air.

Copal is generally imported in large lumps about the size of potatoes. The clearest and palest are selected for what is called *body-gum*; the second best forms *carriage-gum*; whilst the residue, freed from the many impurities with which it is associated, constitutes *worst quality*, fitted only for japan-black or gold-size.

Copal is tasteless and inodorous; transparent and of conchoidal fracture. Heat softens it without rendering it viscid. In alcohol it is but little soluble; but it is said to become more so by reducing it to a fine powder, and exposing it to atmospheric influences for twelve months. Boiling alcohol or spirit of turpentine, when poured upon *fused* copal, accomplishes its complete solution, provided the solvent be not added in too large proportions at a time. The addition of camphor also promotes the solubility of copal; so likewise does oil of rosemary.

Dammara is a tasteless, inodorous, whitish resin, easily soluble in oils. It is not so hard as mastic, with which it forms a good admixture.

Elemi is a resin of a yellow color, semi-transparent,

and of faint fragrance. Of the two resins which it contains, one is crystallizable and soluble in cold alcohol.

Lac constitutes the basis of spirit-varnish. The resin is soluble in strong alcohol aided by heat. Its solution in ammonia may be used as a varnish, when the articles coated with it are not exposed more than an hour or two at a time to water.

Mastic is a soft resin of considerable lustre. The two sorts in commerce are, *in tears* and the *common mastic*; the former is the purer of the two. It consists of two resins—one of which is soluble in dilute alcohol. With oil of turpentine it forms a very pale varnish of great lustre, which flows readily and works easily. Moreover, it can be readily removed by friction with the hand; hence its use for delicate work of every description.

Sandarac is a pale odorous resin, less hard than lac with which it is often associated as a spirit-varnish. It consists of three resins differing as to solubility in alcohol, ether, and turpentine. It forms a good pale varnish for light-colored woods; when required to be polished, Venice turpentine is added to give it body.

Of the solvents of these various resins little need be said. In the manufacture of varnishes great care, as well as cleanliness, are required. The resins should be washed in hot water, to free them from particles of dust and dirt; they should be dried and assorted according to their color, reserving the lightest shades for the best kinds of varnish.

The *linseed-oil* should be as pale-colored, and as well clarified as possible. New oil always contains mucilage, and more or less of foreign matters; as these prevent the regular absorption of oxygen, the oil requires preliminary treatment. The common plan is to boil it with litharge; but such *oil varnish* is inferior to that prepared with sulphate of lead.

The best method is to rub up linseed-oil with dry sulphate of lead in sufficient quantity to form a milky mixture. After a week's exposure to the light and frequent shaking, the mucos deposits with the sulphate of lead, and leaves the oil perfectly clear. The precipitated slime forms a compact membrane over the lead, hardening to such an extent that the clarified oil may be readily poured off.

Turpentine is of very extensive use. The older it is, the more ozonized, the better it is. Turpentine varnishes dry much more readily than oil varnishes, are of a lighter color, more flexible and cheap. They are, however, neither so tough nor so durable.

Alcohol is employed as the solvent of sandarac and of lac. The stronger, *ceteris paribus*, the better.

Naphtha and *methylated spirit of wine* are used for the cheaper varnishes. Their smell is disagreeable. The former is, however, a better solvent of resins than alcohol.

SPIRIT VARNISHES.—Mix—

Alcohol	500 parts.
Ether.....	60 "

Heat in a flask, and suspend therein from a bag, one hundred and twenty parts of finely-divided well oxidized copal. Continue the heat until complete solution takes place.

Such a varnish combines brilliancy and transparency with considerable hardness and solidity. As color is easily generated over the fire, the materials are best digested in a water bath. Such a varnish is, however, only suitable for fancy articles, and is, after all, not equal to a mixture of resins.

A VARNISH FOR PAPER, MAPS, ET CETERA.

	Parts
Spirit of wine,	32
Mastic,	6
Sandarac,	3
Venice turpentine,	3
Pounded glass,	4

Mix the pounded mastic, sandarac, and glass thoroughly together, and place them in a tinned copper digester. Add the alcohol, stir well and frequently with a wooden spatula, and heat for several hours in a water bath. When the solution is complete, add the turpentine, stir frequently, continuing the heat for an hour, and strain when cold through a cloth.

This method is applicable to all spirit varnishes.

A WHITE SPIRIT VARNISH FOR VIOLINS.

Spirit of wine,	One gallon.
Mastic,	Two pounds.
Turpentine varnish,	One pint.

A VARNISH FOR WHITE WOODS.

Bleached shellac,	Three pounds.
Spirit of wine,	Two and a half gallons.

The shellac should be first dissolved in a gallon of the spirit, and the rest added after straining.

ANOTHER VARNISH FOR MUSICAL INSTRUMENTS.

	Parts.
Spirit of wine,	32
Sandarac,	4
Pounded glass,	4
Seedlac,	2
Mastic in tears,	2
Venice turpentine,	2
Elemi,	1

These varnishes may be readily colored—*red*, by dragon's blood; *yellow*, by gamboge. If a colored varnish is required, clearly no account need be taken of the color of the resins. Lac varnish may be bleached by Mr. LEMMING's process:—Dissolve five ounces of shellac in a quart of spirit of wine; boil for a few minutes with ten ounces of well-burnt and recently-heated animal charcoal, when a small quantity of the solution should be drawn off and filtered: if not colorless, a little more charcoal should be added. When all tinge is removed, press the liquor through silk, as linen absorbs more varnish; and afterwards filter it through fine blotting-paper. Dr. HARE proceeds as follows:—Dissolve in an iron kettle about one part of pearlash in about eight parts of water, add one part of shell or seed lac, and heat the whole to ebullition. When the lac is dissolved, cool the solution, and impregnate it with chlorine gas till the lac is all precipitated. The precipitate is white, but the color deepens by washing and consolidation. Dissolved in alcohol, lac bleached by this process yields a varnish which is as free from color as any copal varnish.

One word in conclusion with reference to all spirit varnishes. A damp atmosphere is sufficient to occasion a milky deposit of resin, owing to the diluted spirit

depositing a portion : in such case the varnish is said to be *chilled*.

ESSENCE VARNISHES.—They do not differ essentially in their manufacture from spirit varnishes. The polish produced by them is more durable, although they take a longer time to dry.

Table Varnish may be made as follows :—

Damma resin,	1 pound
Spirits of turpentine,	2 pounds
Camphor,	200 grains

Digest the mixture for twenty-four hours. The decanted portion is fit for immediate use.

COMMON TABLE VARNISH.

Oil of turpentine,	1 pound
Bees' wax,	2 ounces
Colophony,	1 drachm

COPAL VARNISH FOR INSIDE WORK.

Pounded and oxidized copal,	24 parts
Spirit of turpentine,	40 "
Camphor,	1 "

FLEXIBLE COPAL VARNISH.

Copal in powder,	16 parts
Camphor,	2 "
Oil of lavender,	90 "

Dissolve the camphor in the oil, heat the latter, and stir in the copal in successive portions until complete solution takes place. Thin with sufficient turpentine to make it of proper consistence.

OIL VARNISHES.—These, the most durable and lustrous of varnishes, are composed of a mixture of resin, oil, and spirit of turpentine. The oils most frequently employed are linseed and walnut ; the resins chiefly copal and amber, but also the others already recorded.

The drying power of the oil having been increased by litharge, red-lead, or by sulphate of lead, and a judicious selection of copal having been made, it is necessary, according to BOOTH, to bear in mind the following precautions before proceeding to the manufacture of varnish :—1. That oil varnish is not a solution, but an intimate mixture of resin in boiled oil and spirit of turpentine. 2. That the resin must be completely fused previous to the addition of the boiled or prepared oil. 3. That the oil must be heated from 250° to 300°. 4. That the spirit of turpentine must be added gradually and in a thin stream, while the mixture of oil and resin is still hot. 5. That the varnish be made in dry weather, otherwise moisture is absorbed, and its transparency and drying quality impaired.

The heating vessel must be of copper, with a rivetted and not a soldered bottom. To promote the admixture of the copal with the *hot* oil, the copal—carefully selected and of nearly uniform fusibility—is *separately* heated with continuous stirring over a charcoal fire. Good management is required to prevent the copal from burning or becoming even high colored. When completely fused, the heated oil should be gradually poured in with constant stirring. The *exact* amount of oil required must be determined by experiment. If a drop upon a plate, on cooling, assumes such a consistency as to be penetrated by the nail without crack-

ing, the mixture is complete ; but if it cracks, more oil must be added.

The spirit of turpentine *previously heated* is added in a thin stream to the former mixture, care being taken to keep up the heat of all the parts. With proper attention to these directions, the following prescriptions from DUMAS, TOMLINSON, BOOTH, and others, will be found of use :—

COPAL VARNISH FOR FINE PAINTINGS.

Gum copal, fused,	8 pounds
Linseed oil, heated to 250°,	2 gallons

Boil for about a quarter of an hour, until the mixture strings strongly, and then add spirit of turpentine, hot, three gallons. Although much loss of turpentine ensues, the varnish will be so much the more transparent, durable, and drying.

CABINET VARNISH.

Copal, fused,	14 pounds
Linseed oil, hot,	1 gallon
Turpentine, hot,	3 gallons

Properly boiled, such a varnish will dry in ten minutes.

BEST BODY COPAL VARNISH.

Copal, fused,	8 pounds
Linseed oil,	2 gallons
Turpentine, hot,	3½ "

The mixture must be slowly boiled for five hours until quite stringy, and subsequently mixed with the heated turpentine. This varnish is well suited for all objects intended for polishing.

In preparing *artists' copal varnish* it is advisable to separate the particles of copal by means of pounded glass, to prevent the gum from adhering, so that a moderate fire will suffice. The older the turpentine the more drying the varnish. Take—

Finest picked copal,	3 pounds
Pounded glass,	2 "
Linseed oil,	3 quarts
Spirit of turpentine,	5 "

All the before-mentioned varnishes are recommended to be made with clarified, but not otherwise prepared oils. Consequently they take long to dry, and cannot be polished for months. Anime is often introduced to hasten the hardening of the varnish, in the proportion of one part to two of copal. But such varnish is less durable. A yet inferior copal varnish contains anime in the proportion of two parts to one of the former.

WAINSCOT VARNISH FOR HOUSE PAINTING AND JAPANING.

Anime,	8 pounds
Clarified linseed oil,	3 gallons
Litharge,	½ pound
Acetate of lead,	½ pound
Sulphate of copper,	¼ pound

All these materials must be carefully but thoroughly boiled together until the mixture becomes quite stringy, and then five and a half gallons of heated turpentine stirred in.

Such a varnish is, of course, every way inferior to one made with a carefully prepared drying oil, as above prepared by the aid of sulphate of lead. But it exsiccates very rapidly, and is well suited to the common purposes

for which it is intended. It can be easily deepened in color by the addition of a little gold-size.

The varnish used in India for palanquins is made by melting a kind of sandarac, and mixing it with boiling and drying linseed oil. Mr. RHODE, in *Balfour's Cyclopædia*, knows of no better or more durable polish for teak and chittagong wood particularly, than may be prepared by melting three or four bits of sandarac, of the size of a walnut or small egg, and pouring upon it a bottle of boiling linseed oil previously rendered drying by boiling litharge or other dryer, and after boiling them together gently for an hour, adding while cooling a teaspoonful of venice turpentine. If too thick, it may be thinned with spirit of turpentine. It should be rubbed on the furniture, and after a little time—during which it may be exposed to the sun—rubbed off. The friction should be continued daily, and the polish should not be again applied for eight or ten days; after which it may be slightly applied every one or two months. Water does not injure this polish, and any stain or scratch may be rubbed over, which cannot be done with French polish. To give the appearance of gold to silver leaf used by the Condapilly Moochies, for ornamenting boxes, palanquins, *et cetera*, a little aloes is dissolved in the varnish, which is laid over it. A very good varnish is prepared by Moochies with shell-lac and wood oil, heated in small quantities.

French polish is employed upon flat surfaces, and consists simply of a solution of resin in spirit of wine. The simplest sort of French polish may be made by dissolving one and a half parts of shell-lac in eight parts of spirit of wine. Such a polish is very durable, but many other gum-resins are employed. A good dark-colored polish is prepared from one pound of shell-lac, half a pound of gum-benzoin, and one gallon of spirit of wine. Others recommend twelve ounces of shell-lac, three ounces of copal, six ounces of gum-arabic, to one gallon of spirit.

The *lacker* used for wood work or brass is also a varnish. For brass the proportions are half a pound of pale shell-lac to one gallon of spirit of wine. It is better prepared without the aid of heat, by simple and repeated agitation. It should then be left to clear itself, and separated from the thicker portions and from all impurities by decantation. As it darkens on exposure to light, the latter should be excluded. A pale yellow lacker may be made by mixing one ounce of gamboge, and two ounces of Cape aloes, with one pound of shell-lac. For a bright yellow half a pound of turmeric and two ounces of gamboge are required; for a red lacker, half a pound of dragon's blood and one pound of annatto. It need scarcely be said that the color will also be modified by that of the lac employed.

WATER.—*Eau*, French; *Wasser*, German; *Aqua*, Latin.—The poet SOUTHEY thus appositely writes of this all-important fluid:—

Most blessed water! neither tongue can tell
The blessedness thereof; no heart can think,
Save only those to whom it has been given
To taste of that divinest gift of heaven.

In the very first record of that fiat of the Creator, which called forth by omnipotent volition the innu-

merable planetary bodies distributed in infinite space, the primary matter especially mentioned is water: *And the Spirit of God moved upon the face of the waters.* Whether the circumstances of the creation, as related in Genesis, differ from the order observed in giving form to, and producing diversity of, objects upon the earth by the *great First Cause*, is a question which does not affect one way or another, the subject of the present article; although the study of the disposition of the principal objects within the limited range of man's sphere of inquiry, geographically and geologically considered, demonstrates most conclusively, that water has fulfilled functions in the formation of mineralized and other strata in the solid crust of the earth, of undeniable importance. It is not previous to the generation of vegetal and animal life, however, that the importance of water, as an abundant and primary constituent of the globe, can be properly estimated; for it is only in the fulfilment of the higher designs of Providence, such, for instance, as the production and sustenance of vegetal and animal life and organization, that any approach to an adequate notion of the great ends which water serves, can be formed. Without water no organized structure, whether of vegetal or animal, could, in the human estimation of things, preserve its functions and reproduce itself in obedience to the great generic law of Nature. Independently of its essential importance in this respect, water serves another purpose only secondary to it—namely, that of distributing a medium temperature over the whole surface of the earth, conformably to certain physical laws which will be subsequently alluded to, thereby insuring a genial warmth which is absolutely necessary for the development of plants and animals. It may be assumed, that for some such or other similar all-wise dispensations, the extent and quantity of water on the globe greatly surpasses that of the land. It is well known that water is capable of combining with caloric to a great degree; and, owing to the superficies of the globe being to the extent of two-thirds, water, it is evident the chief portion of the heat derived from the sun is stored in this liquid, for the purpose merely of being eliminated gradually to compensate the earth for that which, owing to its superior radiating power, it gives off so freely as to chill it to a degree prejudicial to organized life, unless supplied by winds or air-currents, passing over the surface of large tracts of waters. This capacity of storing caloric possessed by water is subservient in other respects, not only for equalizing the heat of the habitable portions of the globe, but for the distribution of the liquid itself over the arid parts of the earth. For instance, the warm rays of the sun would be unendurable in the torrid zone, were it not that in these regions large quantities of water are evaporated, and that every unit of it thus converted into vapor renders latent or insensible above one thousand units of heat, thus beautifully neutralizing the violent effect of the sun's intense rays. Again, the aeriform moisture ascends obedient to its expansive force, and diverges laterally to colder regions, where the water having parted with a great portion of its acquired temperature, condenses into clouds, and finally falls as rain, hail, or snow, to refresh and nourish life in its multifarious varieties;

whilst a current of air from colder regions loaded with water rushes to the locality whence it was driven, to compensate the loss of moisture, and maintain the equilibrium of temperature. Thus is a beautiful provision for the preservation of organic life and the maintenance of a genial warmth sustained, a provision which, from its regularity and precision, is called a physical law, though in reality a divine and beneficent dispensation.

Water is therefore of primary importance as well in the physiology as in the economy of life, and quite as indispensable as the air breathed from the dawn to the close of man's existence; without them all other provisions of nature would, under existing circumstances, be inadequate to sustain vitality.

HISTORY.—In considering water scientifically, it offers a wide and an interesting field of inquiry to the aspiring student. For a long time many earnest minds were misled regarding its nature, nor was it till almost within the span of the present age—namely, in 1781—that its true composition was revealed. Formerly, philosophers, universally following the footsteps of the ancients, regarded it as one of their elements, though, in later times, some among them were found who considered it transmutable into an earth by repeated distillations, in consequence, as LAVOISIER subsequently proved, of the glass vessels in which the operations were performed, undergoing slight disintegration on the surface, and giving rise to a crust of silicious and other matters contained in the glass. Its real nature lay hidden and subject to conflicting hypotheses till, by the superior powers of deduction, aided by a deep and patient penetration into the secrets of phenomena, according to the principles of chemistry as then understood, CAVENDISH, by most conclusive and beautiful researches, as well synthetically as analytically, revealed its true nature as a compound body. Like all other inventions and discoveries of great importance, there were others ready to claim the honor, such as WATT and LAVOISIER; but evidently the principles which they enunciated appear to have originated with CAVENDISH, and had been communicated through PRIESTLEY and others to the forementioned philosophers, previous to the publication of the account of CAVENDISH'S researches on the subject. The light thus shed upon the knowledge of chemical phenomena, might appropriately be placed in juxtaposition with the brilliant lustre emanating from the discovery of oxygen by a PRIESTLEY, or from that of the atomic theory by a HIGGINS and a DALTON. The phenomena attending the combustion or explosion of hydrogen gas in common air, and the endeavors of WARLTIRE to deduce from the experiment whether or not caloric was ponderable, seem to be the primary facts that led subsequently to the discovery of the composition of water. PRIESTLEY, WARLTIRE, and doubtless others, too, repeated the experiment frequently; and although water was a product in every instance, yet no one before CAVENDISH seems to have given the necessary attention to the question of how this water was formed. After numerous trials regarding the proportions of air and hydrogen that were required to produce this important liquid, CAVENDISH found these to be two volumes of hydrogen and five

of air. Subsequently the research in this direction recommended itself to other philosophers, among whom GAY-LUSSAC fixed the respective quantities of the component gases necessary to produce water at one volume of oxygen and two of hydrogen.

PREPARATION.—When two volumes of hydrogen and one of oxygen gas are mixed in a confined vessel and ignited by means of the electric spark, a slight flash of light and loud explosion follow their combination, and water remains in the vessel to the extent of the weight of the combined gases. In like manner, when hydrogen issuing from a small jet is ignited, and a deep cylindrical glass is inverted on the flame, water is produced; and, owing to it being condensed on the cold surface of the glass, appears first as a slight coating of dew, and subsequently in the form of small drops which trickle down the walls of the vessel. Many other means are now known, whereby pure water from its elements is produced, such, for instance, as transmitting pure hydrogen gas over several metallic oxides inclosed in tubes, and heated to redness. The most conclusive experiment for demonstrating the composition of water is that performed by the aid of the galvanic battery. In this experiment, the constituent gases are evolved at the respective poles of the battery in the ratio of two volumes of hydrogen and one of oxygen; and by mixing these gases in a eudiometer or other tube, and transmitting the electric spark through them, water is again reproduced. It would be tedious to specify the numerous ways in which water can be formed from the combustion of hydrogen. It may be instanced, however, that finely-divided platinum—platinum black—possesses the power of causing the combination of the gaseous constituents of water in a remarkable manner. The principle of DOBEREINER'S instantaneous light is founded on this same property.

The arrangement by which the decomposition of water may be illustrated, consists simply of a glass globe with stopper openings at the sides and at the top, filled with water. Small platinum wires pass through the corks at the sides, and up through the apertures at the top, terminating in flat plates of the same metal. Two graduated tubes filled with water are inverted over these plates, and the zinc and copper poles of a voltaic battery connected with the protruding wires at the side, thus converting the two tubes into ordinary decomposing cells. On setting the battery in action, the water in the tubes will undergo decomposition in part, oxygen being formed on the side of the copper or positive pole, and hydrogen on that of the zinc or negative pole; both gases, as they accumulate, ascend to the closed ends of the tubes, forcing out the water. By reading the index on the tubes, it will be found that the quantity of hydrogen in the tube inverted on the zinc pole will be strictly double the volume of the oxygen in the other; in other words, the elements are evolved in the exact ratio of their existence in water, as may be proved experimentally by exploding the mixture of both gases in a cylinder over mercury.

PROPERTIES OF WATER.—Water, like gases and elastic bodies generally, possesses very varied properties both of a physical and a chemical nature. The knowledge of the former constitutes the chief division

of two correlative branches of the physical sciences, namely, hydrostatics and hydrodynamics; the former relating to the equilibrium, or the statical momentum of this fluid, and the latter, to the order of its motion under unequal forces. As the knowledge of these is more particularly connected with the science of mechanics or engineering, they need not be specially dwelt upon here.

Pure water has neither taste nor smell; it is colorless in small bulk, but of a greenish hue when seen in large masses. Water is solid at temperatures below 32°, liquid between 32° and 212°, and gaseous at a higher heat. By a careful method of reducing the temperature of water, and guarding against any agitation of the liquid or contact with any angular body, the point of solidification descends as low as 8°, or even 5°; that is, 24° and 27° below the point at which it freezes when it is agitated. In like manner, if the ordinary pressure under which it boils at 212°, namely, thirty inches of mercury, be reduced, the phenomenon of ebullition succeeds at considerably lower degrees of heat. Thus it is that on the summit of high mountains, where, in consequence of the elevation, the normal pressure of the atmosphere is lessened, water is observed to boil at a lower thermometric degree than at the base. In the act of solidification water resolves itself into numerous forms, one of which is a rhomboid, closely resembling Iceland spar. Under ordinary circumstances, when its particles are in equilibrium, water is elastic and compressible. This property had long since been proved by OERSTED, and modernly has been established by PERKINS. The results are, however, variously stated: thus, PERKINS found that by a pressure of three hundred and twenty-six atmospheres, the compression amounted to .035 of the bulk, or a value of one hundred and eight millionths for every atmosphere; whereas, when the strain was raised to two thousand atmospheres, the reduction was less than one-half of the above for each atmosphere, namely, forty-one millionths. OERSTED found the average reduction per degree to be forty-five millionths of its bulk; he likewise observed that the contraction increases in direct proportion to the power exercised in compressing it, up to seventy atmospheres. Water is likewise subject to compression and extension when under the influence of another power, namely, that of heat, but with greater irregularity than is observed when acted upon by mechanical force. Generally speaking, the abstraction of heat from bodies serves to bring their particles closer together, and therefore contract them, and *vice versa*; but the axiom is true with regard to water only within certain limits. For instance, when ice is melted by causing it to combine with caloric, instead of expanding with each increment, its bulk suffers a diminution till the temperature of the mass rises to 39·2°, at which degree it has been found to possess its greatest density; on continuing the addition of heat, however, it begins to expand till the boiling point is attained, the acquired bulk in this range being, according to the researches of HALSTROM, one part in twenty-four. The experiment can be easily illustrated by a glass vessel fitted with a narrow tube; the contraction and expansion of the water in the flask being indicated by its descent or rise in the capillary

tube inserted into its mouth. The peculiarity attending a change of temperature in water, between the limits of 32° and 48° may be shown to vary from the expected effects resulting under ordinary circumstances from the addition or abstraction of caloric; thus, the expansion which is observed to take place in the liquid from its point of greatest density, 39·2°, when heated through a range corresponding to that between this and the freezing point, equals exactly that which a reduction of temperature from 39·2° towards the freezing effects, so that the volume at 48° and 32° is exactly the same.

The following table of the contraction and expansion of water between the three points, 32°, 39·2°, and 212°, gives the results arrived at by KOPF:—

Temperature.	Volume.	Temperature.	Volume.
32·0	1·000000	69·8	1·001776
33·8	·999947	71·6	1·001995
36·5	·999908	73·4	1·002225
37·4	·999885	75·2	1·002465
39·2	·999877	77·0	1·002715
41·0	·999883	86·0	1·004064
42·8	·999903	95·0	1·005697
44·6	·999938	104·0	1·007531
46·4	·999986	113·0	1·009541
48·2	1·000048	122·0	1·011766
50·0	1·000124	131·0	1·014100

62·6	1·001010	194·0	1·035397
64·4	1·001184	203·0	1·039094
66·2	1·001370	212·0	1·042986
68·0	1·001567		

This peculiar behavior of water is not only interesting as a curious deviation of a natural law, but because it serves purposes of the highest importance in the economy of Nature. The hardest rocks are split asunder by the freezing and expansion of the water which penetrates their fissures, soils are disintegrated, and their hidden elements of nutrition presented in a state fit for absorption by the roots of plants.

When the great body of water of the globe is cooled on the surface, the exposed portion, owing to its density being slightly increased, sinks, causing the warmer substratum to rise, to manifest the same behavior when its temperature is lowered in like manner. Did this circulation continue till the entire mass acquired a freezing temperature, it is evident that the whole body of water would enter nearly at once into the solid state of ice, to the destruction of all living creatures inhabiting it, to the destruction of oceanic commerce, and of the communion of peoples separated by large tracts of oceans and seas. Further, were such the order of the laws governing Nature, not only would the living inhabitants of waters inevitably perish, but those on the land would also be destroyed, in consequence of the insupportable cold that would be produced in the atmosphere, owing to another property which water, whether in the liquid or solid state possesses, of combining with heat, and rendering it latent or insensible. The warmest seasons would be of little avail to counteract such dire effects, and the genial climate of temperate zones would be changed to a far worse condition than

the frigid regions of the North pole! Providentially, however, the progress of the cooling and consequent circulation induced in water by cold is arrested when the whole mass reaches a temperature of about 40° , that is, 8° above the freezing point; for at this limit, instead of contracting and sinking it becomes specifically lighter by expansion, and therefore remains floating on the subjacent mass. By a continued reduction of its temperature the surface will ultimately freeze, and the crust of ice may go on thickening; but it is inconceivable what cold could thus convert the entire mass into the solid form in this way. Hence, even in the perpetually frozen regions of the North, the water beneath the ice retains a heat of 40° —a temperature much higher than is experienced in this climate often during Winter—and suited not only to marine animals, but calculated, under the least favorable change, to aid in bringing about the normal state of things best suited to the wants of the great family of God's creatures.

From the preceding remarks, the cause of ice—solidified or crystallized water—floating in water will be readily understood. It has been shown that at the point of solidification the liquid has the same, if not a lesser density than at 40° ; but, in passing to the solid state, the gravity is much further reduced, as well by the arrangement which its particles assume, as by the expulsion of the gases dissolved in the water, and which, before they can escape, are enveloped and compressed within the solid crystal. From both, and perhaps other conjoint causes, the density of ice at a temperature of 32° is less than that of water at 212° , and hence the former floats in the latter. At the normal degree at which chemists are accustomed to compare the densities of bodies, namely 60° , and a barometric pressure of the atmosphere of thirty inches, pure water is taken as the standard of comparison, and is expressed by unity, or 1000—compared to this ice has a density of 0.916.

Another circumstance which prevents the freezing of the waters of the oceans is the quantity of saline matters which they hold. DESPREZ found that all such saline solutions have a point of maximum density, which is so far below 39.2° as the solution is richer in salt, and this point of maximum density is even below the freezing point of these solutions when agitated, although in a quiescent state they may be cooled below it without assuming the solid form. The following are the results of his researches on this subject, with solutions of 3.759 parts of the undermentioned compounds in one hundred of water:—

	Maximum density.	Freezing point.
Potassa,.....	21.80	28.22
Carbonate of potassa,.....	24.89	26.22
Sulphate of potassa,.....	27.90	28.24
Carbonate of soda,.....	19.38	26.87
Sulphate of soda,.....	24.21	27.84
Chloride of sodium,.....	24.45	27.02
Chloride of calcium,.....	26.95	26.95
Dry sulphate of copper,....	30.89	29.63

In considering the effects of heat upon water, a further insight into the beautiful provisions of Nature may be obtained. It has been stated in the preceding that water is the medium by which the great heat of warm climates is assuaged. Here it may be well to explain a little more fully how this is effected. Water, of all

known substances, has the greatest capacity for heat—that is, its power of combining with this imponderable, and exhibiting in a less degree its effects in point of warmth than any other body. This property is possessed by it in its several forms of solid, liquid, and vapor or steam. If a given weight of ice, indicating a temperature of 32° be added to an equal bulk of water at 135° , and the mixture be left at rest till the former is melted, the temperature of the mixture on being essayed will not be the mean of the two degrees of heat— 83.5° —as might be anticipated, but it will be found at the same standard as that of the ice itself before its introduction to the hot water. Hence it is evident that ice, or water, in passing from the solid to the liquid state, renders latent as much sensible heat as would bring it to about half the temperature of boiling water, were it in the liquid state at 32° ; or within 52° of boiling water, were it at the normal temperature of 60° . REGNAULT's results on this subject are 142.6° , as the amount of heat rendered latent by water in passing from the solid to the liquid state. All this latent heat is evolved from the water in passing to the solid state of ice; and thus does it beautifully serve to soften the rigor of the cold necessarily felt by those in polar climes. In its liquid state, between 32° and 212° , water manifests the same power of uniting with heat, and showing less of its effects sensibly than any other body. For instance, when a pound weight of water at 100° is mixed with the same weight of itself, of olive oil, and of mercury respectively, at 40° , it will be found that the temperatures of the resulting mixtures will not be the same; the mixture of the waters will show the exact mean of their respective heats before mixing, that is 70° ; but that of the water and oil will be 80° , and of the mercury and water will be 98° . Hence it will be seen that the same quantity of heat which in the last instance produced an effect of 2° on water, raised the same weight of mercury 58° ; and that of 20° in the case of the mixture, water and oil, equalled an effect of 40° on the oil alone. The consequences of this capacity for heat are most important in retaining the temperature of bodies at a medium point, and its value to the human frame in hot climates is almost incalculable; for when taken into the system, or evaporated from the parched and inflamed skin of the inhabitants of dry and arid countries, it reduces the heat of the system more than the same weight of any given substance.

When water is evaporated, the caloric which is thus carried off, and with as little sensible effect as that absorbed by the ice during its transition from solid to a liquid, is very great. Water may be boiled in a vessel, and although heat is transmitted to it, during the period of its evaporation, in a continuous stream, yet the heat of the liquid does not rise beyond 212° , nor does the vapor exceed the same; necessarily, therefore, the whole of the caloric absorbed must be rendered latent in the vapor formed. This may be proved to be the case by transmitting a given weight of the vapor of water—steam—at 212° into a measured bulk or weight of water at any degree, such for instance as 32° or 60° , and noting the effect. In this way it has been found by DULONG to contain as much as 977.4° of latent heat, which, added to its sensible

caloric, 180° —the difference between 32° and 212° —gives a total of 1157 degrees, or units of heat, possessed by every unit of water in the form of steam at 212° . Without dwelling upon the importance in an industrial point of view of this property which water possesses of combining with heat on assuming the gaseous form, and parting with the same wherever this vapor is transmitted to and condensed, or on the power which an accumulation of the vapor at its normal temperature, or at a higher heat, exercises in the thousands of varied forms in which steam is employed in connection with mechanism and industrial works of arts and manufactures—it will be well to cite this property in further proof of the profound beauty of the conception which, as stated in the introduction, has ordained this to be the medium of modifying the rigor of seasons and the influence of the geographical position of lands. Thus the water which is evaporated within the tropics, and which takes up with it an amount of heat corresponding to 1100° , conveys this heat towards the frigid zones, where, on being condensed either into rain, hail, or snow, it is given out to the air and surrounding objects, and thereby greatly contributes to the mildness and habitableness of those parts. Water evaporates not only at 212° , but at all intermediate temperatures between this and its freezing point; and even when in the state of ice, it has been ascertained that it gives off a very rarefied steam. In all these cases the quantity of heat which it renders latent increases with the degree of rarefaction, so that the same weight of steam, or watery vapor, produced at 60° , contains much more insensible heat than when generated at the boiling point of water.

The chemical relations of water are likewise of the utmost importance. In solvent power, that is, its power of overcoming the cohesion of particles of matter, it has no equal; and this force is exercised in reference to gases and liquids, as well as solid bodies; only that in the case of gases, instead of overcoming the cohesive force of the substance, the reverse is the effect, for it is the repulsive force or their expansion that is, so to speak, neutralized. To this phenomenon of destroying the repulsive force of the particles of gases, and the cohesive in solids or liquids, the term *solution* is applied; and, as is well known, it can in some cases be effected by heat, although in these the change is properly designated *fusion*. Water does not manifest the same behavior, however, with all solids, liquids, and gases, so that it appears the particles of the body capable of being affected in this way, must have a peculiar state of molecular aggregation which holds them together with a force inferior to that which water exerts upon them. There are therefore a numerous class of substances that are not affected at all under ordinary circumstances, and others to a very unequal degree, by water in this respect. For instance, a piece of rock crystal, calcareous spar, or glass, will remain in water a length of time without undergoing any change; but a crystal of sugar-candy, alum, or carbonate of soda, will be found to disintegrate readily, and disappear in the liquid. The former are said to be *insoluble*, and the latter *soluble* substances, in reference to water. Of those which are soluble in water, the quantity of them

which the liquid is capable of combining with, till the equilibrium of the cohesion of the substance dissolved is attained—in other words, the point of saturation of the liquid with such a compound, is very variable, though almost in all cases more or less increased by heat. This may be readily proved by adding to equal weights of water, sugar, salt, or chloride of sodium and gypsum, exposing as great an extent of these as possible to the water by stirring the mixture, and then permitting to rest a while. If the solutions, say one pound of each, be evaporated, and the dry residue weighed, it will be found that the saccharine matter will weigh about twelve ounces, the saline residue about five and a quarter ounces, and the calcareous not more than fourteen or fifteen grains. Again, difference of temperature affects the solvent power of water, increasing it—except in few instances, such as when common salt and gypsum are the subjects, and which are nearly equally soluble in cold and hot water—with each additional degree of heat communicated to the liquid up to 212° ; thus nitrate of potassa is dissolved in water at 57° to the extent of one-fourth, at 92° to that of one half, at 131° to an equal weight, and at 212° to the extent of twice the weight of the water employed. When the solutions made at the higher temperatures, however, are allowed to cool, the particles of the solids, over and above what is taken up at the normal degree, regain their cohesive force, and separate in the form of crystalline bodies. These reactions are of particular importance in a chemical point of view, as they offer a simple and ready means of separation and purification of many substances in various branches of manufacturing industry, the principles of which are governed by chemical laws. Another phenomenon connected with the solution of solids in water is, that in several instances a reduction of temperature takes place; while in other cases heat is evolved. GAY-LUSSAC has explained this anomaly. He found that when simple solution was effected of a salt, whether in a hydrated or anhydrous state, cold, or a reduction of the temperature of the liquid, resulted; but when chemical combination took place between the substance and the solvent, as, for instance, in the production of a definite hydrate, a rise of temperature is experienced. In the former case the salt, in passing from the solid to the liquid form, renders a quantity of heat greater or less according to its capacity for this imponderable, latent, and which is abstracted from the sensible temperature of the water; whilst in the latter the chemical force exerted in the act of combination develops an amount of caloric which is greater than that of the latent heat of the body, and hence the rise of temperature. The simple experiment of dissolving nitrate of potassa or chloride of ammonium in water will, with the aid of an ordinary thermometer, illustrate the truth laid down to the reader as regards the cold produced; and of hydrate or caustic potassa or sulphuric acid in reference to the heat developed. This reaction affords a ready means of distinguishing between chemical combinations with, and simple solution of a substance in water. In all these cases, however, with the exception of simple combination, water effects no change in the substance, so that by evaporation of the liquid, the solid

matter may be again obtained, possessing the properties peculiar to it before solution. There are a few instances, however, in which water does not retain this neutral character; for with some of the salts of bismuth, antimony, and tin, its addition produces a decomposition, causing a liberation of the radical or acid of such, while itself in part undergoes decomposition. The reader will find these examples of decomposition illustrated under the respective metallic salts referred to.

To enter into the behavior of water with the alcohols, ethers, oils, resins, and other matters, would prolong the subject beyond prescribed limits; suffice it to say, that when alcohols partake of the nature of oils, they are not at all soluble in it; neither are ethers and oils, in the ordinary acceptation, dissolved by water; nor are the resins. Alcohol—that resulting from the fermentation of saccharine matters—is soluble in it in all proportions, although ether, the derivative of this body, and differing from it only by the elements of one equivalent of water, is almost insoluble in the liquid.

Behavior of Water with Gases.—Not only has water the property of liquefying a great number of solid bodies, but it exercises the same function with respect to many gases; a property that is of very great importance in the economy of nature in many instances.

To convey an adequate conception of the solvent power of water for gases, it may be stated that one hundred cubic feet, or six hundred and twenty-five gallons of water, at 60° and a barometric pressure of thirty inches, will dissolve of—

Hydrochloric acid gas,	50000·0	cubic feet.
Ammonia,	67000·0	"
Sulphurous acid,	5000·0	"
Sulphuride of hydrogen,	300·0	"
Chlorine,	200·0	"
Carbonic acid,	100·0	"
Carbonic oxide,	6·6	"
Binoxide of nitrogen,	5·0	"
Oxygen,	4·6	"
Nitrogen,	2·5	"

Water which has been much exposed to the air, such as rain water, absorbs two and a half parts of that compound; and what is so curious regarding it is, that the amount of oxygen in such, instead of being only twenty-one per cent., as in the atmosphere, was found to be so high as 34·8 per cent. by GAY-LUSSAC and HUMBOLDT. BOUSSINGAULT found that at an elevation of six to eight thousand feet, water absorbs not more than one third of the volume of air which it liquefies on the plain; which behavior has been cited as the cause of fishes not being found in the Alpine lakes situated at comparatively high altitudes; the small amount of oxygen in the soluble state in the water being thought insufficient to support the respiration of these cetaceous animals.

Many natural waters contain considerable quantities of nitrogen. PLAYFAIR estimated that the famous Buxton water, as it issues from the spring, is in combination with nearly three-fourths of its volume of nitrogen—as will be hereafter more discussed under its analysis. With so unnatural a phenomenon, the question, Whence does it come? at once intrudes itself. That it is assimilated from the air is impossible; and it is hardly conceivable that the water in passing through

the calcareous strata of the district should meet with or take up such quantities of nitric acid and ammonia as would, by their mutual decomposition in some such manner as the following—

give rise to the forementioned volume of gas.

Before entering upon the consideration of natural waters with respect to their hygienic qualities, *et cetera*, it may be stated that pure water at 62° and thirty inches barometric pressure, is taken for the standard to which the relative density of all other solids and liquids is compared; just as air is adopted as the standard for measuring the gravity of gases, both being assumed unity, or 1000. At the above degree of heat and pressure, one hundred cubic inches of it weigh 252·45 grains; consequently the imperial gallon weighs 70·000 grains, or ten pounds avoirdupois. It is eight hundred and fifteen times heavier than air, and one thousand three hundred and four times the weight of an equal bulk of its densest vapor, steam, generated at 212°. Its composition is represented as being one equivalent of hydrogen and one of oxygen—HO—and it has been found to contain—

	At. weight.	Centesimally.
1 Eq. hydrogen,	1	11·1
1 Eq. oxygen,	8	88·7
	9	100·0

NATURAL WATER.—By this term is understood the ordinary liquid which serves the purposes of every-day life, whether its source be the rain, hail, or snow, which falls from the atmosphere; the drainings of the surface of the country, accumulated in lakes or rivers; well, or natural springs, through which the liquid permeating the porous strata of the earth at one place, finds an outlet or lower hydrostatic level at another; and sea or salt water. For the sake of clearness in the details which the Editor intends to lay before the reader on this subject, its consideration will be made in the following order, namely, rain, surface—including lakes and rivers—and spring or well waters, all embraced under the class Fresh Water; and Sea Water, or such waters as contain an abnormal quantity of foreign ingredients, and are therefore unfit for the more general uses to which this liquid is applied.

FRESH WATERS.—*Rain and other Waters immediately derived from the Atmosphere.*—As already stated, there is a continual evaporation of water taking place from the surface of the land and sea, which is greater in warm latitudes, and lesser in the parallels approaching the frigid zones and the poles of the earth. This evaporation is dependent, in the first instance, on that curious property of gases, discovered by DALTON, by which a space filled with one kind of vapor or gas, offers as little obstruction to the diffusion of another vapor or gas, in the same space, as if it were already a vacuum; and in the second, upon the temperature. Some other conditions likewise affect the evaporation of water spontaneously, such as the quantity of moisture already contained in the atmosphere, the force and direction of the winds, *et cetera*, which need not be followed. Whilst the heat at which it

was converted into an elastic vapor remains the same, watery vapor is quite as invisible as the air; but on sudden changes of temperature, occasioned by being brought into contact with a colder body of air, or any cooling surface, then the moisture is first condensed into very minute drops, forming clouds, and these drops continue to aggregate among themselves till their gravity becomes greater than the air, and they fall to the earth as refreshing rain. The theory of HUTTON, with respect to rain being produced by the mixing of opposite currents of air at different temperatures, though true to some extent, appears to be inadequate to produce the amount of rain which the numerous meteorological observations so generally made during late years have registered; and it is therefore supposed that more rain is formed in close proximity to the earth, than in the higher regions of the air. The experiments of Professor J. PHILLIPS corroborate this in an extraordinary manner. He found that the fall of rain on the—

Top of York Minster, 242 feet high, was 15·910 inches.		
Roof of Museum, 73 "	20·461 "	
Surface of ground, 0 "	24·401 "	

That all the rain of these latitudes could not be produced on Dr. HUTTON's principle, may be readily conceived by considering the circumstances a little in detail. The tension of the vapor of water at 59° equals 0·5000 of an inch of mercury, and at 41° 0·2573; now, if equal bulks of air at these temperatures, saturated with water, commingle, the mean temperature of 50° will be attained, at which the tension of the aqueous vapor is 0·3608, the difference between which and 0·3786, the mean of the tensions above indicated, that is, 0·0178, represents the tension of the amount of water that would be condensed from the state of vapor. This quantity is very inconsiderable compared with that resulting from atmospheric changes which take place on or near the earth, as may be seen from the following example, quoted from GRAHAM. The mean temperature of January in this country is about 34°, but with a South-west wind the thermometer may be observed to rise gradually in the course of forty-eight hours to 54°; now, supposing such wind to be saturated with aqueous vapor, and that in traversing over the surface of the land it is cooled to 34°, the amount of moisture which it must deposit will be very considerable, as appears by the following—

Tension of vapor at 54° equal to 0·429 inches mercury.	
Do. do. 34° "	0·214 "

Difference condensed as rain,	215 "
-------------------------------	-------

Invariably there is the greatest average fall of rain near the equator; it diminishes towards the poles, as the latitude is higher. The average annual fall of rain at—

New Granada, 12° 0' N.....	is 126 inches.
Calcutta, 19° 46' N.....	81 "
Rome,.....	39 "
England, average.....	31 "
London,.....	23 "
St. Petersburg,.....	16 "
Uleaborg,.....	13½ "

Snow and hail is a form of rain, in which the water is frozen before it reaches the earth; the former results from the formation of clouds at temperatures below 32°, wherein the minute drops are crystallized into an infinity of spiculæ, which arrange themselves into regular lines and figures, diverging from one another at angles of 60° and 120°. They are all referable, however, to the hexagonal and prism shape, though the details differ in almost every storm.

Hail is supposed to be formed in warm weather, when the sun is above the horizon, and under different circumstances to those calculated to produce snow. It is supposed to be produced in the ascending current of greatly rarefied air, by the cold consequent on such rarefaction, the force of the upward current being such as to carry with it the minute solid globule, till, by uniting with others, it attains a density that causes it to descend. Generally, this phenomenon of the production of hail is associated with a peculiar electrical state of the atmosphere, to which it must be principally attributed.

Rain, as it descends from the clouds, is contaminated with various gases and vapors which it dissolves from the air. The atmosphere, normally composed of oxygen and nitrogen, contains vast quantities of ammonia, carbonic, nitrous, and nitric acids, besides other gases and vapors which arise from the number of chemical phenomena which are ever taking place on the surface of the earth. The principal of the *abnormal* gases is *carbonic acid*—a gas which escapes in enormous quantities from volcanic districts, and which results also from respiration, from the combustion of fuel, and decay of organic matter and vegetal growth generally, on the surface of the earth. Though analysis detects only about one thousandth of this gas in the air, still when the total bulk of the latter is taken into consideration, the entire weight of carbonic acid disseminated in it is enormous, averaging more than *five billions of tons*! The air likewise contains much *ammonia* and vapors of the oxides of nitrogen, besides other unknown gases and vapors, which escape from decomposing animal and vegetal matter.

All the gases which have been detected in atmospheric air are exceedingly soluble in water; hence it follows, that rain-water, as it descends through the lower strata of the air, must become to a great extent impregnated with these gases. LIEBIG has shown that even snow contains much ammonia, and recently in some rain-water, collected on Brighton Downs, MEDLOCK detected this gas, and also traces of the acids of nitrogen, which had probably resulted from the oxidation of a portion of the volatile alkali. It is, therefore, evident that water as it falls from the clouds, whether in the form of snow or rain, is not absolutely pure, but contains much carbonic acid and ammonia. Probably traces of other gases, which have hitherto eluded detection, are likewise present. Not only is ammonia present in snow and in rain, but HOKSFORD even detected it in large quantities in the ice from the Glacier de Boisson, at a height of twelve thousand feet above the level of the sea; and MEDLOCK has found marked quantities of this volatile alkali in the purest and most transparent masses of ice from the Wenham Lake in

America. The presence of ammonia in rain-water has not long been known; and it is one of the main causes of the fresh and invigorating influence of it upon the vegetal creation.

SURFACE WATER.—Rain-water is a very powerful solvent of certain ingredients of the soil, such as sulphate of lime, chloride of sodium, and magnesian salts; but when saturated with carbonic acid, as is ordinarily the case, its solvent properties are remarkably increased. For example, ordinary water, free from carbonic acid, will not dissolve more than a grain of chalk per gallon; but when saturated with that gas, the same quantity will dissolve upwards of two hundred grains. In like manner it is found that carbonate of magnesia, which is almost entirely insoluble in ordinary water, will dissolve in water impregnated with carbonic acid in very considerable quantity. Hence, in addition to the alkaline chlorides and sulphates, and sulphate of lime, nearly all spring-waters are found to contain carbonates of lime and magnesia, which are held in solution as bicarbonates by the carbonic acid derived from the soil and atmosphere. Certain of the mineral constituents impart to water its *hardness*. These are the salts of lime and magnesia. By the hardness of a water is understood the power it possesses of decomposing soap; and according to the quantity of soap decomposed by a given quantity of water before the remaining soap becomes available as a detergent, so is its relative hardness. The sulphates, chlorides, and nitrates of lime and magnesia give to the water the so-called *permanent* hardness, while the carbonates, which are held in solution by excess of carbonic acid, impart to it its *temporary* hardness, or that which it loses by boiling.

The waters of rivers, from which the greater number of English cities and towns obtain their supplies, contain the above-named mineral constituents in quantities varying according to the composition of the soil over which they flow. In the water of streams which have their sources in the primitive rock formations, as, for instance, the rivers Dee and Don, there is found only from two to eight grains of mineral constituents per gallon. The water of the Trent, which flows through a *selenitic* district, contains about sixty grains of sulphate of lime; while in the water of the Thames, which is derived from, and flows over a chalk formation, there are only about three grains of sulphate, and from eight to ten grains of carbonate of lime per gallon. For the sake of comparison, and in illustration of the above statement, the analyses of the Thames, Trent, Dee, and Don are given:—

	Thames water.	Trent water.	Dee water.	Don water.
Carbonate of lime,	10.80	0.32	0.85	2.23
Sulphate of lime,	3.00	21.55	0.12	0.13
Nitrate of lime,	0.17	—	—	—
Carbonate of magnesia, . .	1.25	5.66	0.36	1.07
Chloride of sodium, . . .	1.80	17.63	0.72	1.26
Silica,	0.56	0.72	0.14	0.52
Iron, alumina,	0.27	0.50	0.06	0.27
Phosphate of lime,	trace	trace	trace	trace
Organic matter,	2.36	3.68	1.64	3.06
	20.21	50.06	3.89	8.54
Hardness,	14.00	26.50	1.50	3.00

From the preceding analyses it is evident that the proportions of mineral constituents are, in a great measure, dependent upon the nature of the soil over which the water flows. Although the opinions of chemists differ widely regarding the hygienic effects of an access of the mineral constituents in water, the Editor is inclined to believe—and this opinion almost universally prevails—that so long as the proportion does not exceed thirty grains per gallon, they are decidedly more beneficial than injurious. The sense of taste is perhaps the best guide; and so long as preference is given to a water containing mineral matter to such as are almost entirely free therefrom, it may be assumed that such waters are the best for general purposes.

These remarks apply equally to the waters derived from wells. Indeed, in all the water supplied for man's use there are found the above-mentioned mineral constituents. Are they there for no purpose? Would Nature contaminate water with constituents injurious to health? It has been already mentioned that such waters as contain a certain proportion of mineral constituents, are much more refreshing and agreeable to the taste than those in which they are absent. The remarkable investigations of modern chemists have shown incontestably that a certain proportion of mineral elements in food is absolutely necessary for the due performance of the vital functions. In milk, man's natural food, there are all the elements necessary for the formation of the body—phosphate of lime for the formation of bone; salts of soda to aid in the formation of the gastric juice, and to give fluidity to the blood; casein to form the flesh; and butter to produce fat. In all the cereal grains and in the vegetables which constitute the chief food of graminivorous animals and of man, there are found the *same* mineral constituents which occur in water—*man's natural drink*. Who, then, can deny the value of mineral constituents in the water of wells and rivers? When in very large excess, as in the *shallow* well-waters of London—an exception to the rule—they may, perhaps, tend in some measure to derange the digestive organs of delicate persons, especially of those who have been accustomed to the use of softer water—that is, such as contains less earthy salts—for dietetic purposes; but in most cases in which hard waters are found to disagree, the objectionable effects may, in all probability, be ascribed with greater truth to *organic* impurities than to the actual *mineral* constituents. Having thus briefly alluded to the physiological effects of the mineral constituents of water, it becomes necessary to enter more fully into the nature of the more abnormal *organic* contaminations to which the water of wells and rivers is exposed, since on these is essentially dependent the hygienic character of the water—its fitness for domestic purposes.

NATURE OF THE ORGANIC MATTER CONTAINED IN WATER.—All river and well waters contain more or less of organic matter, which is acknowledged to be a predisposing cause of disease. The separation of these impurities from water is a problem of high scientific interest, and one that has engaged the attention of all the eminent chemists of the day.

The great importance of this subject in a sanitary

point of view renders it necessary to enter into detail regarding it :—

1. The source of organic matter.
2. The nature of the decomposition it undergoes.
3. The means of destroying the organic matter and rendering the water pure and wholesome.

1. *The Source of Organic Matter.*—A river is the natural drain of the country and towns through which it flows, and the organic matter the water contains must necessarily be derived from the three following principal sources :—

From the sewage of towns ; from the surface drainage of manured and cultivated lands ; and from the decay of the aquatic plants and animals which inhabit the streams.

The sewage of towns consists mainly of the urine and fæces of man and animals, the refuse of gas-works and numerous manufactories, which are diluted with the refuse water which has been used for domestic and manufacturing purposes. The Thames, which may be taken as a type of other rivers, before it reaches London drains an area of four thousand square miles, and receives in its course the sewage of towns containing upwards of seven hundred thousand inhabitants. It flows, moreover, through a richly cultivated country, from which it derives vast quantities of organic matter. It is further contaminated with the products resulting from the decomposition of aquatic plants and animals. Hence it is obvious that the water of the Thames, even before it reaches Teddington lock, must be most seriously contaminated with putrefactive organic matter. That much of the organic matter which enters the river is spontaneously decomposed is undoubted, otherwise the river would be little better than a filthy sewer ; but that a vast quantity remains in solution in the water as now supplied to the inhabitants of London, is equally a demonstrable fact, as will be seen by the analyses and experiments detailed in the following pages.

Most, and indeed all the companies who take their supply from the Thames, filter the water through sand and shingle previously to pumping it into the mains. By this means most of what exists in it in the form of undissolved or *mechanically suspended particles* is removed, and the water is consequently to some extent improved in appearance. But the greater part of the organic matter is *dissolved* in the water, and is not separated by mere filtration. That much organic matter exists in the present supply is evident from the decided color which the water possesses. This is also the case with the Pike water at present supplied to Liverpool.

If a tall tumbler be filled with any of the water now supplied to London, Liverpool, Manchester, and other towns, and placed on a sheet of white paper, the water will be seen to possess a yellowish or brownish tinge, occasioned by *the organic matter which is held in solution*. The removal of this organic matter, which is doubtless a fertile source of disease in those who daily drink it, is a problem of the highest interest to solve, and one to which MEDLOCK has devoted several years in the hope of its elucidation. Accident in some measure led him to follow out an inquiry into this subject,

which promised to lead to most important results, and the Editor deems the circumstances which suggested this investigation worthy of being recorded ; especially as the results arrived at by accurately conducted experiments are not only of high scientific interest in themselves, but, practically applied, are of great hygienic and national importance.

In September, 1856, he was requested by the directors of the Amsterdam Water Company to analyse several samples of water from the city of Amsterdam. Complaints had been made of the water by several of the inhabitants. It possessed a peculiar *fish-like* smell ; and although perfectly transparent and colorless, and free from the slightest chalybeate taste, it was found, after standing some time, to deposit a reddish-brown sediment, which coated every vessel in which the water was placed.

The service-pipes being of iron, the deposit was assumed to consist of the sesquioxide, resulting either from the decomposition of a protosalt of iron in solution, or from the attrition of the iron pipes through which the water was conveyed.

It may be observed that Amsterdam is supplied with water from the *Dunes*—sand-hills—in the neighborhood of Haarlem. Trenches, five miles in length, have been dug on the sides of the hills, to intercept the rainfall. The water is conveyed to a large reservoir, whence it flows to the filterbeds at the works, and is there filtered through four feet of filtering medium, consisting of pebbles, shells, and fine sand. After filtration it is pumped up an iron standpipe one hundred and fifty feet high, and conveyed thence by iron mains to Amsterdam, a distance of eighteen miles.

Five samples of the water were sent for analysis—one from the works *before the water came in contact with iron* ; the other four from various standpipes in the city.

In the water from the works, before it came into contact with iron, the quantity of iron oxide, alumina, and phosphates amounted to 0.95 grain per gallon. In the analysis of the four other samples, *after passing* through eighteen miles of iron pipes, the quantities were reduced in the several determinations to 0.09, 0.07, and 0.07 grain, and in the fourth sample to an unweighable trace. Thus, instead of taking up an additional quantity of iron oxide from the mains and service-pipes, the water was found actually to have lost nearly the whole of the iron which it previously held in solution ; but, notwithstanding the almost entire precipitation of the iron actually in solution in the water which had passed through iron pipes, it formed the objectionable red deposit on standing, while the water from the works, holding in solution nearly half a grain of iron oxide per gallon, formed no such deposit : therefore it was, *à priori*, to be assumed that the red deposit could not consist of oxide of iron, and consequently it appeared necessary to examine this deposit very carefully both chemically and microscopically. The precipitate from ten gallons of water was collected in a porcelain capsule, evaporated to dryness on a water-bath, and heated subsequently in an air-bath to 248° Fahr., until it ceased to lose weight. On ignition, the precipitate *charred* and

was almost entirely consumed, leaving only a minute quantity of ash, consisting of silica, alumina, iron oxide, and carbonates of lime and magnesia.

The small quantity of this deposit at command did not admit of a quantitative analysis. The deposit having been found to consist almost entirely of organic matter, a portion of it, which had been separated from one gallon of water, was examined under the microscope, and was seen to consist of the filaments of dead and decaying algæ, *confervæ*, and other microscopic plants in various stages of decay, and varying in color, like autumnal leaves, from green through pale-yellow, orange, red, brown, dark-brown to black. Many of the fibres retained a perfectly organized structure, and in some the spores, by which these plants are propagated, were distinctly visible. Amongst these plant remains were numerous silicious tubes, which had probably invested the delicate filaments of the algæ while living.

It appeared highly important to determine the *cause* of the precipitation of the organic matter from the water which had been in contact with the iron pipes; and in the hope of elucidating this interesting question MEDLOCK proceeded to Amsterdam to inspect the source of supply and the works. As anticipated, the Dune canals were found to be actually choked up with aquatic plants, and at the sides and wherever the current was sluggish were large masses of dead algæ floating on the surface. The sand at the bottom, originally very white and pure, was blackened to some depth by decaying vegetal matter, and, when disturbed, numerous bubbles of fetid marsh gas escaped.

The water had the peculiar fish-like smell of the masses of *flab—ulva intestinalis*—floating on the surface. The stones on the sides of the canals, the hurdles placed to keep up the banks, floating pieces of stick, and indeed every *solid* body with which the water came in contact, were coated with a reddish-brown deposit, similar to that which was found to separate from the filtered water in Amsterdam. *This deposit was observed to be particularly abundant near the iron sluice gates.* A pipe from one of the mains in the city was examined at the same time, and found to be coated on the inside with a thick slimy deposit of vegetal remains, which presented under the microscope an appearance exactly similar to that of the deposits above alluded to.

Remembering the important fact established by SCHÖNBEIN, that copper and platinum in a finely divided state have the property of converting ammonia into nitrous acid; and MEDLOCK having demonstrated that *lead* in any form possesses a similar power—it occurred to him that if the same property were possessed by iron, it would throw some light on the separation of the organic matters from waters which are placed in contact with that metal. SCHÖNBEIN, however, states that iron, before it produces a similar oxidizing effect on the ammonia, requires to be heated to redness. But in the course of an extensive series of experiments, it has been found that iron pyrophorus *instantly* transforms ammonia into nitrous acid; and in pursuing the inquiry further, it was found that strips of sheet iron placed in water containing ammonia or

organic matter capable of yielding it, act almost as energetically as the metal in a finely-divided state.

Having proved that metals possess this remarkable power of oxidizing ammonia, and converting it into nitrous acid, and, bearing in mind the extraordinary oxidizing power of this acid, even when present in minute quantities, it appeared to MEDLOCK that he had arrived at a simple and effectual means of depriving water of all organic impurities by thus accelerating a natural process of decay. The facts just mentioned appeared to merit a thorough investigation, and the results arrived at will sufficiently prove that he did not, in the first instance, attach too much importance to them. In order to study the action of iron upon the Amsterdam water, he submitted to analysis a quantity of this water which *had never been in contact with iron*, and at the same time he immersed several coils of iron wire in two gallons of the same water. The water in which the iron wire was placed was perfectly bright and free from color, and had nothing visible in mechanical suspension except a few of the siliceous tubes already alluded to. The experiment was made in four open glass bottles. A series of remarkable phenomena were observed. In five minutes a faint white cloud was seen radiating from the coil of wire, and descending in the form of a parachute. In half an hour the cloud had increased in density, and the water became opalescent. In six hours the cloud assumed a brownish color, and there was a brown deposit at the bottom of each of the bottles. The cloud continuing to increase during forty-eight hours, assumed more and more a flocculent character, and a reddish color, exactly like the deposit from the water which had flowed through the iron pipes. The water was now filtered through fine Swedish filter-paper and submitted to analysis, and a portion of the deposit examined under the microscope. The latter consisted of the remains of algæ, each separate flock having a siliceous tube as a nucleus. The remainder of the deposit was burned, and the ash found to consist of oxide of iron, silica, and the carbonate of lime and magnesia.

The following are the analyses of the water before and after being in contact with iron:—

	I. Water from the Dune canals. Grs. per gal.	II. Same water, having been in contact with iron forty-eight hours. Grs. per gal.
Sulphate of lime,.....	3.70	3.68
Chloride of sodium,.....	4.10	4.01
Carbonate of lime,.....	5.60	3.20
Carbonate of magnesia,.....	3.97	1.30
Silica,.....	0.16	trace
Iron, alumina, and phosphates,	0.95	trace
Matter, volatile on ignition—so called organic matter,.....	2.10	trace
	20.58	12.19

By these analyses it is seen that the 2.10 grains of organic matter contained in the water *were decomposed or thrown down by contact with iron.* The water, thus purified, no longer had the unpleasant fish-like taste and smell which had marked its previous contamination.

A portion of the water which had been in contact with the iron wire was rendered slightly alkaline by

pure alcoholic potassa, evaporated to dryness, and the residue tested for nitrous acid. The paper became instantly blue from the liberation of a trace of the nitrous acid formed by the oxidation of ammonia, and which had been instrumental in destroying the organic matter.

In the residue of the water which had *not* been in contact with iron and still containing its organic matter, no indication of nitrous acid could be obtained.

The Amsterdam water, the water of the Thames, and indeed that of nearly all other rivers, contain much organic matter, which may be divided into two classes—*nitrogenous* and *non-nitrogenous*. The latter, consisting of carbon, oxygen, and hydrogen, may be represented by the general formula— $n(\text{CHO})$; and, when no longer under the mysterious influence of the vital force, are rapidly resolved into carbonic acid and water. The nitrogenous class being chiefly of animal origin, and composed, in addition to the above-mentioned elements, of nitrogen, sulphur, and phosphorus, may be represented by the general formula— $n(\text{CHONSP})$. Now, when animal matter decays, and when dissolved in water, decomposition proceeds very rapidly; beside carbonic acid and water other and very offensive products are eliminated. As a general rule, the carbon unites with oxygen to form carbonic acid; and with hydrogen, to form marsh gas or carbide of hydrogen; hydrogen and oxygen unite to form water; nitrogen and oxygen with hydrogen to form ammonia; sulphur with hydrogen to form sulphide of hydrogen; phosphorus with hydrogen to form phosphide of hydrogen.

The latter two are exceedingly offensive to the sense of smell, and are, moreover, highly poisonous. Thus in the spontaneous decomposition of the organic matter contained in water there are produced carbonic acid, carbide of hydrogen, ammonia, sulphide of hydrogen, and phosphide of hydrogen. These are the *recognized* compounds; but when it is borne in mind that the gaseous emanations of decomposing animal matters are infinitely more offensive to the sense of smell and injurious to health than any of the gases above mentioned, or of any combination of them, it can only be concluded that the effluvia of decaying organic matter contain other constituents, of which the true character has not yet been determined. Thames water, if allowed to stand in an open vessel for a few days in warm weather, acquires a very offensive odor, arising from the decomposition of the animal and vegetal matter which it holds in solution.

This water, notwithstanding, is considered by maritime authorities to be the very best for the use of ships' companies. On board ship the water is stored in wooden casks, which are placed low down in the hold. During the first week or fortnight, according to the temperature of the atmosphere, the water ferments, evolves a quantity of gas of offensive odor, and deposits a copious brown sediment. The water gradually ceases to smell badly, becomes bright and sparkling, and will then keep fresh and sweet for an indefinite length of time. In other words, it loses by a natural process of decay, the whole of its *putrescent impurities*. In vessels of war, and in most of the large steamers, tanks of iron have been substituted for casks of wood for storing

the water necessary for the use of the passengers and ship's company. In iron tanks Thames water evolves *no offensive gases*, but becomes much purer than when stored in wood, and deposits a more copious brown sediment, which turns red on exposure to the air. The gases produced in the wooden casks are said to be slightly luminous in the dark, and to explode when a lighted candle is incautiously placed near the bung-hole, when the plug is removed. The luminosity is due to phosphide of hydrogen, and the explosive character of the gases to carbide of hydrogen.

As the organic matter was found to be so effectually removed by iron from the Amsterdam water, MEDLOCK instituted a series of experiments upon the water of the Thames. The water operated upon was that supplied to his laboratory by the Grand Junction Company. On placing some of this in contact with iron in glass bottles, precisely similar phenomena were observed as in the case of the Amsterdam water, but the deposit was *black*, and was formed more quickly. The next step in the investigation was to test the water before and after contact with iron for the great destroying agent, NATURE'S SCAVENGER, *nitrous acid*. The residues of six separate gallons of the water were examined for nitrous acid as follows:—Each residue, mixed with half an ounce of water was introduced into a Florence flask, fitted with a cork and long funnel tube. In the neck of each flask was placed a slip of bibulous paper, moistened with starch paste and iodide of potassium. Through each funnel tube was added half an ounce of dilute sulphuric acid, one part strong acid, and nine parts water, to liberate the nitrous acid, if present; but no indication of that gas was found, as the test papers remained perfectly white. Six other gallons of water drawn at the same time, were placed in open bottles, with two ounces of fine iron wire, and left for forty-eight hours. The waters were then filtered from the deposits, evaporated to dryness, and tested for nitrous acid in a manner similar to the preceding, and with the following results:—

- Experiment 1.—Paper becomes blue in ten minutes.
 “ 2.—Paper becomes blue in five minutes.
 “ 3.—Paper becomes blue in four minutes.

As it appeared probable that the nitrous acid liberated by the sulphuric acid might remain in solution, and in consequence not instantly affect the test-paper, in experiments with the residues of the other three gallons of the water *hot water* was used, and an acid of double strength. In each of these experiments the test-paper became blue in a few seconds.

These results prove beyond a doubt the production of nitrous acid by the action of iron upon the nitrogenous compound contained in the water. The Editor submitted masses of the Pike water to a similar treatment, and found results that confirmed in every respect those attained by MEDLOCK. Why is not this plan of purification adopted by the Water Committee in Liverpool?

EXAMINATION OF THE BROWN DEPOSIT PRODUCED BY IRON.—The brown deposits from three separate gallons of Thames water were collected in porcelain crucibles, and dried at 248° , till they ceased to lose

weight. When thoroughly dried they weighed as follows:—

NO. I.	NO. II.	NO. III.
4·4352 grains.	4·4243 grains.	4·4350 grains.

They were then separately analysed with the following results centesimally:—

	I.	II.	III.
Organic matter,.....	22·92	24·87	23·87
Sesquioxide of iron,....	65·36	63·20	64·39
Carbonate of lime,.....	11·11	11·04	11·20
Carbonate of magnesia, traces	trace	trace	—
Silica,.....	0·59	0·49	0·53
Loss,.....	0·02	0·31	0·01
	100·00	100·00	100·00

In order to arrive at a correct knowledge of the action of iron upon Thames water, MEDLOCK made a series of daily determinations of the mineral residue and organic matter in the water supplied to his laboratory, with the following results:—

	Solid residue. Gra. per gallon.	Organic matter Gra. per gallon
Jan. 4th, 1857,.....	20·867	2·248
Jan. 5th, 1857,.....	19·573	1·740
Jan. 6th, 1857,.....	21·159	1·424
Jan. 7th, 1857,.....	20·127	1·401
Jan. 8th, 1857,.....	21·452	3·249
Jan. 9th, 1857,.....	20·374	2·756
Jan. 10th, 1857,.....	20·920	3·062
Average,.....	20·638	2·268

At the same time as the water was drawn for the last analysis, he placed three separate gallons in wide-mouthed bottles.

Into the first gallon was put a coil of fine iron wire, weighing half an ounce. After standing two hours the water was filtered, and on being analysed in the usual way, gave—

Solid residue,.....	17·372 grains.
Organic matter,.....	1·232 do.

A second gallon with one ounce of wire for two hours gave—

Solid residue,.....	16·693 grains.
Organic matter,.....	1·170 do.

A third gallon with eight ounces of wire for two hours gave—

Solid residue,.....	13·182 grains.
Organic matter,.....	0·950 do.

In other experiments, too numerous to detail, the water was exposed to the action of a *large surface of iron* from twelve to forty-eight hours; and as a general result it was found that by allowing water to remain in contact with a large surface of iron for about twelve hours, every trace of organic impurity was destroyed, or converted from the soluble to an insoluble condition, in which state it admitted of being effectually removed by ordinary filtration.

After the preceding details on the nature of the organic impurities contained in ordinary well and river water, the offensive gases arising therefrom, and the functions of the numerous microscopic plants and animalcula which are contained in them, it now remains to describe the means that MEDLOCK has adopted for

placing the results of his discoveries at the service of the public.

PRACTICAL APPLICATION OF THE FOREGOING PRINCIPLES.—It has been proved by numerous trials with Thames water, sewage, and water artificially contaminated by mixing therewith sulphide of hydrogen, sulphide of ammonium, and urine, that however impure a water may be, it can be rendered perfectly pure and wholesome to drink by merely allowing it to remain in contact with a large surface of metallic iron for twelve or twenty-four hours, and then filtering through well-washed sand; or, better still, through a mixture of about one part animal charcoal and four parts sand.

The plan above stated is applicable to the purification of the supply of water to towns, as well as to small quantities for domestic and manufacturing purposes. To brewers, dyers, starchmakers, soda water and lemonade manufacturers, *et cetera*, a supply of water free from color and organic impurities is an essential requisite; and the Editor after long and careful study of the numerous processes recommended for purifying water, prefers the one above detailed, as being at once the most simple, easy, and effectual.

The following table exhibits in round numbers the degrees of impurity in water, used for the supply of towns in England, Scotland, *et cetera*, each degree being equal to one grain per gallon—

Distilled water,.....	0°
Loch Katrine,.....	2·0
Dee—Aberdeen,.....	4·0
Tay—Perth,.....	5·5
Dumfries,.....	7·0
Gorbals,.....	8·0
Leven,.....	8·5
Clyde,.....	9·5
Tyne—Newcastle,.....	11·0
Tweed—Coldstream,.....	11·5
Seine—Paris,.....	12·0
Liverpool well, purest,.....	13·0
Glasgow “ “.....	15·0
Kilmarnock,.....	15·0
Thames—1854,.....	15·5
“ —1851,.....	21·0
Glasgow well, most impure,.....	96·0
Liverpool well, “.....	417·0

Disease occasioned by the Organic Impurities of Water.—Dr. HASSALL remarks—In proof that water highly charged with decomposing organic matter frequently gives rise to severe and fatal diseases, often of an epidemic character, one is able to produce abundance of evidence. To occasion these effects, no doubt the organic matters, animal or vegetal, resolve themselves into carbide, sulphide, and phosphide of hydrogen, cyanides, *et cetera*, as well as other lethal products, and these disarrange the whole functions of the body. To enter more minutely into this part of the subject would be out of place in a technological work.

Disease occasioned by the Metallic Impurities in Water.—The Editor has known most serious illnesses to arise from water containing lead. Many hard as well as soft waters act injuriously upon lead, consequently, as a general rule, water should never be stored in cisterns of this metal. Why use lead when one can have slate cisterns and enamelled iron pipes? A

gentleman and his family residing in the neighborhood of Liverpool were constantly ill, but whenever they left home they recovered. The water was supposed to be the cause, and was tested from time to time, and pronounced good. The amount of lead was small, and had been overlooked—as is very often the case with inexperienced analysts. On examination of several gallons of the water—it was a remarkably soft water—lead was detected. The Editor recommended slate cisterns and enamelled iron pipes, and from that day to this all the ill effects of the water disappeared.

Microscopic examination of Water.—Most well and river waters, when allowed to stand in an open vessel for several days, especially in warm weather, deposit a sediment more or less copious, in which may occasionally be discovered, by means of a microscope, a vast number of the lower forms of animal and vegetal life, which have been made the subject of special study by several able microscopists, and especially by Drs. HASSALL and LANKESTER. Much misapprehension, however, appears to prevail regarding the extent to which these lower forms of organic life occur in water. In works treating on this subject, it is usual to group a large number of these objects together in a circular drawing, which convey the impression, and are generally understood to represent the animalcula contained in a single drop of water. Nothing, however, can be more erroneous, and nothing more calculated to convey false notions regarding the character of the water supplied to the public.

It appears to be a law of nature, that wherever the conditions of life exist, there life will manifest itself in forms suited to the circumstances. If a portion of earth be brought up from the deepest mine, and exposed for some time to the combined influence of heat, light, and moisture, various forms of vegetal and animal life will appear, even if the soil be entirely excluded from contact with the surrounding atmosphere. In the water of rivers containing animal and vegetal matter in a state of decay, are presented all the conditions of life; and hence the numberless forms of the lower organisations which are met with. That these are injurious to health, no one can venture to affirm; but their presence may form, to some extent, an index of the quantity of putrefactive organic matter which may be present. In cases where it is necessary to examine a water microscopically, the following is the plan recommended by the Editor:—

About a quart of the water to be examined should be placed in a conical glass vessel, very narrow at the bottom, in shape something like a tall champagne glass, and covered over with paper. After remaining at rest some hours, a slight deposit will generally be observed at the bottom; and in this deposit will often be seen numerous small animalcula moving about with wonderful rapidity; these have been named by naturalists *Cyclops quadricornis*. They are particularly abundant during the summer in river waters containing much organic matter. Other crustacea are also abundant, amongst which may be mentioned various species of *Daphnia*, which, by their number, often give a marked yellow color to water. Of radiate animals, the hydra and other forms of zoophytes are frequently

present. The fresh water sponge—*Spongia fluviatilis*—frequently occurs in great abundance. Numerous lower forms of the vegetal kingdom often abound in river waters, especially in those of shallow streams. These belong chiefly to families Confervaceæ, Dismidiæ, Diatomaceæ, and Fungi. Many of these lower organisms are beautiful objects under the microscope, and well worthy of the attention of all lovers of nature. Space will not allow of any detailed description of the almost numberless species found in water; they have been only briefly alluded to with the view of pointing out the fact, that when they occur in water used for dietetic purposes, they must be regarded as a proof of the presence of dead and decaying organic matter, and must not be looked upon as the only kind of contamination of the water. Their function appears to be to destroy the numerous organic matters which are present. To examine well the deposit formed in the conical glass, the clear water should be siphoned off, and a portion of the deposit placed in the field of the microscope—a quarter-inch glass is perhaps the best for such observations.

Dr. HASSALL examined several specimens of water, both upwards and downwards in the course of the river Thames from London, and they brought to light the singular and important fact that Thames water, from Brentford in one direction to Woolwich in an opposite,

Fig. 613.

swarms with living productions, principally of the genus *Paramecium*, and of one species of this genus *P. chrysalis* of EHRENBURG.

The engraving exhibits the principal animal and vegetal productions contained in the Thames water at Richmond, drawn with the camera lucida, and magnified two hundred and twenty diameters.

The subjoined cut exhibits the more remarkable vegetal and animal productions found in the water of the Thames at Waterloo Bridge.

Fig. 614.

Color of Water.—In rivers the impurity of water is frequently visible to the eye. It is often of a red color, as it flows through rocks of red marl which contain much oxide of iron in their composition. It descends milky from the glaciers of Iceland and the slopes of the Andes, because of the white earth it holds in suspension. It is often grey or brown in the muddiest English rivers. It is always brown when it issues from boggy lakes, or runs across a peaty country, as at Rivington Pike. It is occasionally black to the eye when the amount of vegetal matter is excessive, as in the Rio Negro of South America; and it is green in the geysers of Iceland, in the Swiss lakes, among the islands of the South Sea, and around Great Britain and Ireland. Only in clear and deep water, like those of the Bay of Naples, and in parts of the Pacific, where minute objects may be seen on the bottom some hundreds of feet down, is the real blue color natural to water in large masses distinctly perceptible. This is the deep blue which is seen in the *grotto azzura* of the island of Capri, in the Bay of Naples, and in the deep indigo waters of some parts of the Mediterranean and Adriatic seas.—*Johnston.*

THE ADDITION OF CHEMICAL AGENTS TO WATER.—This head includes several proposed methods of purifying water, which consist in the addition of certain chemical agents to this liquid, by which its composition is altered.

Addition of Alum.—In England, as well as in France, a popular method of clearing muddy water is

to add a few grains of powdered alum to it; two or three grains are usually sufficient for a quart of water. This process is called *alunage de l'eau*; and ARAGO states, that when practised on the Seine water, it causes the mud to agglomerate in long thick striæ, which are very quickly deposited. The theory of the process appears to be this:—The alum decomposes the bicarbonate of lime, and gives rise to the formation of sulphate of lime, which, with sulphate of potassa, remains in solution, while carbonic acid is evolved, and hydrate of alumina being precipitated in a flocculent form, carries with it various mechanical impurities.

This method, then, is a kind of mechanico-chemical one. It clears the water, but at the same time alters its chemical composition, and by converting bicarbonate into sulphate of lime, augments the hardness of the water.

Addition of Caustic or Carbonated Alkalies.—Caustic alkalies, added to water holding in solution bicarbonate of lime, saturate the excess of carbonic acid, throw down carbonate of lime, and leave an alkaline carbonate in solution. If soda be the alkali used, the results will be as follows:—

If an alkaline carbonate be employed, all the earthy salts—calcareous and magnesian sulphates, chlorides, bicarbonates, and carbonates of the earths—are precipitated, while alkaline sulphates, chlorides, and bicarbonates which do not communicate hardness to water, are left in solution. If carbonate of soda be employed, its reaction on sulphate of lime and chloride of magnesium will be as follows:—

Addition of Lime.—A few years ago, Professor CLARK of Aberdeen took out a patent for the purification of water. His process consists in the addition of caustic lime to water, by which the bicarbonate of lime held in solution is decomposed; the caustic lime saturates the excess of carbonic acid, and forms carbonate of lime, which is precipitated.

The Editor believes the process of CLARK to be *virtually impracticable on the large scale*, while its efficacy is but slight.

It must be remembered that this mode affects the bicarbonate of lime, not the more troublesome earthy salts, such as the sulphates and chlorides, on which the hardness of spring waters mainly depends. The difficulty of mixing lime and water, in definite proportions, on the large scale, must be obvious to every one. If too much be employed, the companies would supply their customers with *lime-water*! If too little, the bicarbonate of lime would not be completely destroyed, and the process would be a failure. Altogether, the difficulties of carrying out the process will ever prevent its adoption on a large scale.

Addition of Oxalate of Potassa.—Mr. HORSLEY of Cheltenham, some years ago, took out a patent for a new method of preventing incrustations in boilers, and also for depurating, filtering, and otherwise rendering water more fit for drinkable and other purposes. When sea-water is taken for generating steam, he purifies it by employing oxalate of potassa and ammonio-phosphate of soda; and the proportions he uses for the water of the British Channel are about two drachms of oxalate of potassa to about two ounces of the ammonio-phosphate of soda for every gallon. When his object is to februate and soften hard water, he employs such substances as are capable of decomposing the calcareous salts, such as calcined or caustic baryta, or baryta water, phosphate of soda, silicate of potassa, oxalic acid, or the oxalates, and caustic strontia, or strontia water; but he gives the preference to oxalate of potassa. He first ascertains the degree of hardness of the water, and then adds the requisite quantity of oxalate of potassa, by which an oxalate of lime is precipitated; and there remains in solution, instead of the lime thus displaced, a carbonate, sulphate of potassa, or chloride of potassium, as the case may be, and the water is purified and fit for use.

The following equation explains the reaction of oxalate of potassa; the salt is assumed to be neutral on bicarbonate and sulphate of lime:—

HORSLEY's patent process does that which CLARK's fails to do: it decomposes all the earthy salts on which the hardness of water usually and mainly depends. But it is open to still greater objections than those that have been raised to the other method. Besides being, like CLARK's, process virtually impracticable, it would prove very expensive, and as regards the metropolitan river-waters, it is quite unnecessary. Moreover, the idea of *physicking* or *doctoring* water, by the addition to it of a poisonous agent, would, if even no other objection existed to this scheme, be quite fatal to it. For though, in the hands of competent persons like Mr. HORSLEY, no possible injury could arise from its use, yet the public would always have some suspicion of water thus treated; and, as a celebrated English engineer observed to ARAGO, water, *like Caesar's wife, should be above suspicion*, which the Rivington Pike

water supplied to Liverpool is not. Liverpool was formerly supplied with spring water from the red sandstone, beautifully cool and refreshing, and free from organic matter. Now the inhabitants are forced by a stubborn water committee to drink a mixture of the *rock* and *surface* water—how the people suffer it is to the Editor a mystery—the latter certainly *blasting its wholesome brother*. The small town of Flint, North Wales, has infinitely better water than is supplied to any of the principal towns of England.

Purification and Filtration of Water.—JOHNSTON says truly, that the water used by a nation or country is an important matter in a well-considered and long-adjusted diet. It by no means follows in all cases, perhaps not even in the majority, that the *purest* water—see *Distilled Water*—is the best for the health of a given family, or for the population of a given district. The bright, sparkling, hard waters which gush out in frequent springs from the chalk and other limestone rocks are relished to drink, not merely because they are grateful to the eye, but because there is something exhilarating in the excess of carbonic acid they contain and give off as they pass through the warm mouth and throat, and because the lime they hold in solution neutralizes or counteracts acid matters in the stomach, and thus acts as a grateful medicine to the system.

On entering upon the purification and filtration of water, it may be stated as an axiom that *the best filter is no substitute for bad water*; still, as various towns throughout the kingdom are supplied with bad water, that is, water containing chemical and mechanical impurities, the Editor deems it necessary to explain to the reader how to remove these wholly or in part, so as to *better* the water. The depuration of water is greatly aided by repose, by which various suspended or mechanical impurities are allowed to subside gradually, and from these the supernatant fluid is drawn or siphoned off. Tanks, cisterns, and reservoirs become therefore important depurating agents. The purification of water by subsidence and decantation is the simplest of all methods of februation; but unfortunately it is a very slow one. It is stated that the water of the Garonne, taken when the river is swollen, does not regain its natural limpidity after a fortnight of perfect rest. The larger particles, of course, quickly deposit, but the finer ones precipitate very tardily. During the time that deposition is occurring, the water is exposed to the air, and consequently undergoes a chemical metamorphosis. The bicarbonate of lime which is dissolved in it parts with a portion of its carbonic acid, and carbonate of lime precipitates:—

In this way the atmosphere assists in softening those waters, which owe the whole or a portion of their hardness to the above calcareous salt. The atmosphere, however, is a source of contamination as well as of purification, and it is on this account that the Editor always condemns the use of *surface* water for dietetic purposes. EHRENBURG states that, exclusive of inorganic substances, he has detected three hundred and twenty species of organic forms in the dust of the

winds. It is obvious, therefore, that waters which are chemically very pure, must become contaminated by exposure in deposit reservoirs.

What are the best methods of purifying water on a large scale?

The water, says TOMLINSON, used for culinary, domestic, and industrial purposes, is exclusively derived from the rain which falls upon the earth, whether the immediate source of supply be the cistern, the well, the spring, or the river. Rain-water is usually so pure, that the action of the most delicate chemical tests is required to detect any foreign substance in it; so that, if cisterns were formed of proper materials, and the rain fell directly into them in sufficient quantity, no better water could be desired. But as the exposed surface of cisterns is too small to collect rain-water in any quantity, it is usual to discharge into them, by means of gutters and shoots, the water which falls upon the roofs of houses; and, as these are covered with dust, insects, and other impurities collected during dry weather, the rain-water of cisterns is thus contaminated in various ways. In some places the rain-water, collected on the surfaces of extensive roofs and flats, is made to pass through a bed of porous materials on its way to the cistern, and thus the solid impurities are strained and separated before the water is used by the public. Such is the case with the large cistern of the ducal palace at Venice.

Wells may be compared with cisterns; but the channels which discharge rain-water into them are not formed of masonry, brick, or metal, but of the rocks which exist immediately beneath the surface. These rocks may be porous, or may abound in minute fissures, through which the rain-water, sinking through the soil, finds a passage; and being divided into innumerable liquid threads, it dissolves and carries along with it a portion of whatever soluble matter it may encounter. Hence, the water obtained from wells is not rain-water, properly so called; it is usually as clear and limpid, but it contains nearly always certain substances in solution, which vary according as the geological structure of the country differs. The same remark applies to springs: their water is rain-water, which, after having traversed strata of greater or less thickness, is sent up to the surface by the pressure of the water in the neighboring hills or other elevations. The nature and proportion of the impregnation to which spring-water is subjected, depend also on the extent of its transit and the kind of rock traversed. The action of rain-water upon certain kinds of rock leads to the production of mineral springs; and if the water descends to a certain depth in the earth, its temperature will be so much raised by the internal heat, that on reappearing at the surface, it will be as a thermal spring.

In filtering on a large scale, for the supply of a city, for example, the cost and durability of the filter are important considerations. On the great scale of Nature, the rocks which filter the water, as it falls upon the surface of the soil, constitute a vast permanent filter, the durability of which arises from the great extent of superficial or subterranean surface concerned. It might at first view appear to be easy to imitate this natural operation, and pass the muddy water of a river through

the porous rock or sand which forms its banks; but this is often an expensive proceeding, on account of want of permanence of an artificial structure so contrived. Toulouse is supplied with water from the Garonne in this way, and it has cost upwards of forty thousand pounds at various times for supplying a city of only fifty thousand inhabitants. The cause of failure in this and other instances arises from the fact already noticed, that when water percolates sand, it deposits its solid impurities to a certain depth between the interstices of the filtering medium, rendering it necessary from time to time to renew the sand. This is illustrated by some experiments conducted by Mr. WICKSTEED. A sand filter which yielded at the rate of ten the first week, yielded nine the second week, six the third week, and only two the fourth week; so that a large natural filter—as this description of filter is called—may go on for some years, yielding a good supply of water, and then gradually diminish it until it ceases altogether. Hence the construction of these so-called natural filters requires much caution on the part of the engineer; and it will always be difficult, if not impossible, to calculate before hand the amount of water which a natural filter proposed to be erected will yield.

A second system of filtration on a large scale consists in the formation of extensive beds of sand of great thickness, resting on beds of gravel, *et cetera*. At intervals of time, from ten to fourteen days, the water is run off; and the filth which had accumulated during filtration is scraped off with a certain thickness of the sand of the filtering bed. Once or twice a year the whole of the sand removed is replaced. This method is costly, and not altogether satisfactory.

Of all the permeable substances used for filtration, animal charcoal possesses in the highest degree the combined mechanical and chemical influence. In addition to its power, in common with other filtering media, of removing suspended or mechanical impurities, it also abstracts from the liquid which percolates it, various *dissolved* bodies, and thus effects a metamorphosis in the chemical composition of the fluid which traverses it. These important properties of animal charcoal have oftentimes led to its use as a filtering medium for water; and hence it is introduced into many of the ordinary domestic water filters. But its deodorizing and decoloring power is soon lost; and, in order to enable it to reacquire its original efficacy, it requires to be re-formed.

There can be no doubt that of all known permeable bodies, the only ones which present all the requisites of filtering media for water on a large scale, are sand and gravel. They are cheap, allow the rapid passage of water through them, and, when *they have been previously well washed*, communicate no taint to the waters which traverse them. Their employment must have been suggested to man by the observation of the numerous limpid springs which are seen in arenaceous districts.

Their action, however, is chiefly *if not entirely* mechanical. They possess little or none of that power of effecting chemical changes on the liquids filtering through them, which animal charcoal possesses in so pre-eminent a degree. Yet, unless several distin-

guished writers have grossly deceived themselves, sand is not entirely devoid of this chemical influence. WAGENMANN, for example, found that when vinegar was filtered through pure quartz sand, the first portion of liquid that percolated was deprived of almost *all its acid*; and the vinegar did not pass through unchanged until the sand had become well charged with acid. The same authority also states that potato-brandy diluted with water, and filtered through quartz-sand, yields at first pure water, then a mixture of water and alcohol deprived of its fusel-oil; and, lastly, the original mixture unaltered. BERZELIUS filtered a saline solution through a long tube filled with sand, and found that it ran out more or less completely deprived of salt. MATTEUCCI repeated BERZELIUS' experiment, and confirmed his statement. He filled a tube about twenty-six feet long with sand, and filtered a saline solution through it; and he found that the density of the liquid introduced by the upper aperture of the tube was to that of the liquid escaping from the lower end, as 1.00 to 0.91. But he observed that this difference of density was not always maintained; for, after a certain time, the saline solution becomes as dense at its exit from, as at its entrance into the tube, proving that the decomposition of the saline solution takes place in the first action of contact between it and the particles of sand. But a still more remarkable result, the inverse of the one just stated, was obtained by the last-mentioned chemist, with a solution of carbonate of soda. He filled a tube nearly ten feet long with sand, and filtered a solution of carbonate of soda through it; and he found that the density of the liquid at its entrance was to that at its exit as 1.000 to 1.005. In this case, then, the sand had deprived the solution of part of its water, and had thereby increased the gravity of the liquid which percolated. Assuming, however, the accuracy of all these reported observations, it cannot be doubted that, *in a practical point of view*, the efficacy of sand, as a filtering medium, depends on its *mechanical, not on its chemical influence*.

Domestic Filters.—In coming now to notice small filters for domestic purposes, such a multitude of inventions and contrivances start up to view that, as TOMLINSON says, how to choose and where to begin is difficult. There are certain classes of subjects, says the same authority, on which the genius of inventors seems to run riot. *Filters* form one of these, and *fire-escapes* another. In either class examples are as numerous as the attempts to solve the problem of perpetual motion, or to square the circle. Almost every kind of porous substance has been enlisted into the service of filters. The animal, vegetal, and the mineral kingdoms have each contributed. Charcoal—animal and vegetal—sponge, flannel, cotton, straw, hemp, saw-dust, wood shavings, branches and leaves, various kinds of porous stone, sand, pounded glass, zinc and iron filings, are a few only of the materials that have been recommended or used; and the methods of employing them are as various and as dissimilar as the substances themselves. The Editor considers the best filter for home use to be that of FORSTER of Liverpool, which he employs in his own house. The water percolates a fine porous stone, which removes all mechanical impurities, and

imparts a freshness to the water, which is not the case when sponge, charcoal, and other substances are the filtering media. It is, as TOMLINSON states, remarkable that very few filters were exhibited in the foreign department of the Great Exhibition. France sent three—two of stone and one of charcoal. An ingenious form of filter was exhibited by the Wenham Lake Ice Company, which consisted of a siphon, the extremity of the short limb of which is furnished with a box containing the filter, so that on inserting this into a cistern or cask holding water, and applying suction at the extremity of the longer limb, a stream of filtered water can be obtained, which may be arrested or drawn at will by shutting or opening the tap, as seen in the figure. In the laboratory, unsized paper is almost exclusively employed as a filtering medium. Other substances, such as flannel, tow, sand, pulverized glass, may occasionally be used.

An arrangement is also made for retaining the liquor in the filter at the same height, until the whole of the fluid to be percolated is expended. To insure this, the menstruum to be passed through is held in a flask inverted, the neck of which, as the reader will perceive by the wood-cut, dips into the liquor already contained in the funnel. As the liquor descends, and the neck of the flask becomes uncovered, a bubble or two of air enters; more liquor exudes, until the neck becomes again immersed, and all communication with the air is again cut off.

VESSELS FOR CONTAINING WATER.—Lead and other metals are very useful to store water in. The Editor is very glad to find, however, that the clean, inexpensive, and beautiful material, slate, is coming into use for cisterns, instead of lead, which is a dangerous metal to have in contact with a liquid of such daily and universal consumption.

DISTILLED WATER.—Certain technical and analytical purposes demand that the water employed by the operator or analyst be perfectly pure. To insure this, distillation is resorted to, by which operation the foreign matters held in suspension or solution are separated. Dr. NORMANDY remarks, that the distillation should be arrested when the salts begin to precipitate; for if the process were continued, part of these saline matters might suffer decomposition, and thus contaminate the distillate. The annexed table from NORMANDY shows the characteristics of pure water. It must not become turbid, or produce a precipitate with any of the subjoined reagents:—

Baryta water—If a precipitate or opaqueness appear, carbonic acid is present.

Chloride of barium—Shows sulphates.

Nitrate of silver—Indicates chlorides.

Oxalate of ammonia—Evidences lime salts.

Sulphide of hydrogen, solution made slightly acid—Antimony, arsenic, tin, copper, gold, platinum, mercury, silver, lead, bismuth, cadmium.

Sulphide of ammonium, solution alkalinized by ammonia—Nickel, cobalt, manganese, iron, zinc, alumina, chromium.

Chloride of mercury, chloride of gold, sulphate of zinc—Prove organic matter.

Pure distilled water, evaporated on a piece of platinum foil, *should leave no residue*. As a drink it is insipid, and is not recommended except in some cases of calculi.

The following table, embracing the composition of some principal river and well waters, will prove interesting to the reader :—

Physiological Effects.—Water is an essential part of the blood and of the living tissues. It is from this liquid that the tissues derive their properties of extensibility and flexibility. It gives fluidity to the blood, and enables the transportation of organic particles from one part of the body to another to be effected. Lastly, it contributes to most of the transformations which occur within the body. Considered dietetically, aqueous drinks serve several important purposes in the animal economy: they repair the loss of the watery part of the blood, caused by evaporation and the action of the secreting and exhaling organs, and thereby assist the stomach in the act of digestion. If, however, they are swallowed in excessive quantity, they may impede digestion by diluting the gastric juice. It is not improbable that water acts as a real nutritive agent, that is, assists in the formation of the solid parts of the body. As an agent for the communication or abstraction of heat to or from the body, water has been before noticed. Furthermore, the influence of atmospheric humidity modifies the character of climates.

Water moderately warm, and which neither cools nor heats the body, acts locally as an emollient, softening and relaxing the various tissues to which it is applied. When swallowed, it allays thirst, becomes absorbed, mixes with and thereby attenuates the blood, and promotes exhalation and secretion, especially of the aqueous fluids. Administered in large quantities, it excites vomiting. The continued excessive employment of water has an enfeebling effect on the system, both by the relaxing influence on the alimentary canal, and by the excessive secretion which it gives rise to. Injected into the veins in moderate quantities, tepid water has no injurious effects; it quickens the pulse and respiration, and increases secretion and exhalation. Large quantities check absorption, and cause difficulty of breathing and an apoplectic

condition. Thrown with force into the carotid artery, it kills by its mechanical effects on the brain.

Besides the dietical and thermotic purposes for which water is employed in medicine, it serves as a diluent, humectant, emollient, evacuant, and, in pharmacy, as a solvent. Water, or bland aqueous fluids, are employed in some cases of poisoning. They serve to dilute the acrid and irritant poisons, the intensity of the action of which on the stomach they lower. Moreover, the presence of aqueous fluids favors the expulsion of substances by vomiting. In preternatural dryness and rigidity of parts—for example, of mucous surfaces, the skin, wounds, and ulcers—water and mild aqueous fluids are useful moisteners and emollients. The copious use of water augments the quantity of fluid thrown out of the system by the cutaneous and pulmonary surfaces, and by the kidneys. If the object be to promote diaphoresis, external warmth should be conjoined with the internal use of diluents; whereas, when one wishes to excite the renal vessels, the skin should be kept cool. In inflammatory affections of the urinary passages, the free employment of aqueous fluids is advised, with the view of diluting the urine, and thereby of rendering it less acrid and irritating. What is called water-dressing may be regarded as a modified and improved form of poultice. It consists in the application of two or three layers of soft lint dipped in water, and applied to inflamed parts, wounds, and ulcers, the whole being covered with oil silk or Indian rubber, which should project beyond the margin of the lint to retain the moisture, and prevent evaporation. Dr. MACARTNEY considers it to operate differently to a poultice; unlike the latter, he says, it prevents or diminishes the secretion of pus, checks the formation of exuberant granulations, and removes all pain. Moreover, the water is not liable to become sour like a poultice, and does not injure the sound part. Water

is frequently employed in pharmacy for extracting the active principles of various medicinal agents.—*Pereira*.

MINERAL AND OTHER WATERS.—GLOVER justly remarks that few subjects connected with medicine are more interesting to the general reader than that of mineral waters. The circumstances attending their administration, the natural mode of their production, the scenery in which they are often placed, and the associations frequently surrounding them, combine to give them, as remedies, an interest exceeding that of ordinary medicinal agents. Hygiene and medicine, in the narrow acceptance of the terms, join hand in hand at the salubrious fountain. Spas have been exalted, and are still exalted by interested parties, as panacean cures for all diseases; others unworthily decried; source has been pitted against source, and pump against pump; and battles fought between biassed spa-doctors, which only tended to raise doubts in the opinions of thinking men.

To enter largely into the subject of natural and artificial mineral waters would be quite out of place in a book of this description, and it would be incompatible with the assigned limits to give more than a general insight into their nature, character, composition, and manufacture. The great *furor* for saline and other springs is daily abating; a very striking proof of this being evidenced at Cheltenham, to which thousands used to rush yearly to partake of its waters, whereas now it is almost entirely deserted. The same, no doubt, will soon be the case with other places, and artificial will, in many cases, supply the place of natural waters. Is not more due to the diet, change of scene and air, than to the virtues said to be possessed by certain springs? What miraculous cures are stated to have been produced by the water of Holywell, Flintshire, North Wales; and yet analysis reveals *nothing* particular in this spring to impart to it medicinal properties, as illustrated by the annexed tabulated results of Mr. JAMES BARRATT, pupil of the Editor—

Free carbonic acid, 10.338 grains, = 21.874 cubic inches.	

This famous spring is the first in Great Britain; it never freezes, and scarcely varies in the quantity of water it emits, drought or wet weather, flinging out *twenty-one tons a minute*.

PEREIRA remarks—Mineral waters were known to mankind in the most remote periods of antiquity, and were employed medicinally both externally and internally. HOMER speaks of tepid and frigid springs. The *Æsculapide*, or followers of *ÆSCULAPIUS*, accord-

ing to SPRENGEL, erected their temples in the vicinity of mineral and thermal waters. HIPPOCRATES mentions mineral waters, although he does not prescribe them when speaking of particular diseases. Their medicinal properties are spoken of by PLINY.

The principal source of saline waters is the rain, snow, hail, dew, percolating a certain portion of the soil, and dissolving various matters in their passage, so as to reappear on the surface at the bottom of declivities as spring-water; or when procured by sinking pits or wells—well-water. But springs are sometimes observed, continues PEREIRA, under circumstances which are inconsistent with the supposition of their atmospheric origin. The boiling springs, says GAIRDNER, which emerge on the verge of perpetual snows at an altitude of thirteen thousand feet above the level of the sea, as in the Himalayas, cannot be derived from the air.

Mineral waters, of course, procure their particular and distinctive properties or qualities from the strata through which they flow. Those of the primitive formation are almost all thermal, generally possessing a high temperature, while those of the older secondary formations are generally cooler. The hot or thermal waters are those possessing a degree of heat more or less raised above the mean of the latitude or elevation at which they are found, and the changes of which, if any, observe no regular periods coincident with the revolutions of the seasons. Three causes, says PEREIRA, have been assigned as the source of the temperature of mineral waters, namely, volcanic action, now in existence; volcanic, now extinguished, but the effects of which still remain; and a central cause of heat, which increases in descending from the surface to the interior of the earth. The *Geysers*, or boiling springs of Iceland, are evidently the result of volcanic action.

PEREIRA proceeds—The origin of the saline and other constituents of mineral waters is another interesting topic of inquiry connected with the natural history of mineral springs. As water, in its passage through the different strata of the globe, must come in contact with various substances which are soluble in it, one refers certain constituents of mineral waters to solution and lixiviation merely, as chloride of sodium, carbonates of lime and magnesia, oxides and bromides of sodium and magnesia, iron, silicic acid, *et cetera*. Chemical action must, in some cases, be the source of other constituents. Sulphide of hydrogen is most likely the result of the action of water on some metallic sulphide, especially iron pyrites; sulphurous or sulphuric acid from the oxidation and combustion of sulphur, free or combined. In acidulous or carbonated waters the carbonic acid probably arises from the decomposition of chalk either by heat or sulphuric acid. The disintegration of chlorides of sodium or ammonium would eliminate hydrochloric acid, while carbonate of soda, found so largely in the native lakes of Egypt, might, as BERTHOLLET supposes, be proved by the action of chloride of sodium or carbonate of lime; thus—

GAIRDNER states that the different orifices of the Karlsbad Sprudel discharge annually about thirteen thousand tons of carbonate of soda and twenty thousand tons of sulphate of soda, in a crystallized state; and further adds, that a very simple calculation is sufficient to prove that the Donnersberg alone, the highest of the Bohemian Mittelgebirge, a cone of clinkstone two thousand five hundred feet in elevation, eviscerates soda sufficient to supply the Karlsbad waters for more than thirty thousand years.

The Editor agrees with PEREIRA that the best classification to adopt is that of grouping mineral waters into four classes, *videlicet*, chalybeate, sulphurous, acidulous, and saline.

CHALYBEATE OR FERRUGINOUS WATERS.—These terms are applicable to those waters, the active principle of which is *iron* in considerable quantity. These waters possess a styptic taste, and when they contain the protoxide of the metal, yield, with ferrocyanide of potassium, a *white* or bluish-white precipitate; and if the sesquioxide be present, they give a *blue* precipitate with ferrocyanide of potassium, and become *red* with

the alkaline sulphocyanide. The carbonated chalybeates are of two kinds, those containing the carbonate of iron, associated with much carbonic acid, which renders them acidulous and effervescent. The Pyrmont, Trinkquelle or drinking spring, Schwalbach Spa, and Pouhon, are of this nature.

The noneffervescent ones are Oddy's saline chalybeate at Harrowgate, the Islington Spa near London, and the waters of Tunbridge Wells. These are also sulphated chalybeates, but they are not of so much importance.

SULPHUROUS OR HEPATIC WATERS.—The most celebrated of these waters are—in England, those of Harrowgate, the appended analyses by Dr. A. W. HOFFMANN being given; Scotland—Moffat and Rothesay; of the Continent—Enghien, Barèges, Aix, near Geneva, Aix-la-Chapelle, and Baden. They have the disagreeable smell of rotten eggs, and give, with salts of lead, bismuth, copper, *et cetera*, black precipitates.

Subjoined are analyses by Dr. HOFFMANN of several of the most important saline chalybeates at Harrowgate:—

The sulphide of hydrogen exists in the above waters, partly free and partly combined. Only a portion can be expelled by ebullition. The amount of the sulphide of hydrogen in the waters varies, which may be partly due to influences affecting the strata through which the waters ascend; to a great extent, however, they must be ascribed to the action of the air.

The general operation of these waters, says PEREIRA, is stimulant. They are adapted for chronic complaints, and are supposed to possess a specific power over the cutaneous and uterine systems, and are said to be beneficial in chronic rheumatism and gout. As previously remarked, would not an iron salt, judiciously administered, act just as well in the above-mentioned diseases?

ACIDULOUS OR CARBONATED WATERS.—The name here implies waters charged with carbonic acid. Most waters contain a few cubic inches of carbonic acid in the gallon, but the acidulous will eviscerate from thirty to two hundred cubic inches. It is stated by ALIBERT that the waters of Saint Nectaire hold four hundred cubic inches in one hundred of the water.

Carbonate or bicarbonate is contained in waters of this kind, and, when this is the case they are called *acidulo-alkaline*. The Selters, Altwasser, Salzsbrunn, Reinerz, and Pymont acidulous waters are of this description. Protocarbonate of iron is sometimes present in them, classifying them under *acidulous carbonated chalybeates*. The spring at Ilkeston, near Nottingham, is the only water of the above class in Great Britain.

Acidulous waters are cooling, refreshing, and exhilarating, and oftentimes relieve nausea. The acidulo-alkaline waters are useful in the lithic acid diathesis, in gout and rheumatism, *et cetera*.

SALINE WATERS, according to PEREIRA, may be divided into five kinds:—

Purging Saline Waters.—Sulphates of soda or magnesia are the active ingredients of these waters: some owe their efficacy to sulphate of magnesia, others to sulphate of soda.

Bitter Purging Waters, Bitter Waters, Bitter-Salt Waters.—Sulphate of magnesia predominates in these waters. Epsom and Scarborough in England, and Seidlitz, Saidehütz, and Püllna on the Continent, are of this kind. Some thermal springs, as those of Acqua del Pozzeto, near Pisa, contain sulphate of magnesia.

Glauber Salt Waters.—Some writers give this name to those waters holding sulphate of soda in solution. Some of these are warm, and on this account are called the *warm alkaline glauher salt waters*. To this division belong the famous springs of Carlsbad,

now so much resorted to for good—or evil! Further on analyses are given of the Carlsbad water, and of several others of the leading and well-known Continental springs. Some of this class of waters are devoid of alkaline properties, but contain, besides sulphate of soda, various earthy and alkaline salts. They are the *earthy glauher salt waters*. To this division belong the deserted springs of Cheltenham, and those of Leamington and Spital.

In large doses the waters of this kind are mild cathartics. PEREIRA says they are useful in diseased liver, dropsical diseases, *et cetera*.

Salt or Brine Waters.—The characteristic ingredient of these springs is chloride of sodium. Iodine or bromine, or both, have been found in some of them, and these most likely add to their medicinal effects. The small quantity of iodine recently found in the water of St. Ann's Well at Great Malvern, Worcestershire, by the Editor, is doubtless the active ingredient in that water.

The Kreuznach and Salzhausen springs in Germany are among the brine springs, and in England the principal ones are at Middlewich and Nantwich in Cheshire, Shirleywich in Staffordshire, and Droitwich in Worcestershire.

Taken in large quantities, saline or brine springs are emetic and purgative. They have been principally celebrated in glandular swellings. The water of Baden Baden contains a large quantity of chloride of sodium.

Analysis of the water of Baden Baden by the Editor:—

	Imperial gallon. Grains.
Alumina,.....	trace
Carbonate of iron,.....	1.356
“ lime,	14.184

Calcareous waters are stimulant, alterative, and constipatory. Externally they are said to be beneficial in the cure of rheumatism, gout, chlorosis, chronic skin diseases, *et cetera*.

The quantity of nitrogen gas accompanying this water has been previously alluded to. Dr. ROBERTSON, in treating of the physical characters of the Buxton waters, ascribes their brilliancy when drawn to the quantity of gas *held in solution*. Of course, this must be fallacious, for very little gas is *held in solution* or *dissolved*. As GLOVER remarks, what occurs in the baths, where a quantity of the nitrogen has been forced along by the current of water, three hundred gallons per minute, furnishes no indication of the amount of *gas in solution*. The great use of the Buxton water is, of course, externally, but upon what its effects mainly depend *still remains unexplained*.

Mr. J. ARMITAGE PEARSON, the eminent consulting surgeon of Buxton, has informed the Editor that he does not look upon the *nitrogen* in any water to be an effective element; and although one sees the gas constantly gurgling forth in strong streams, still Mr. PEARSON agrees with the Editor, that being an *insoluble* gas, it is not absorbed into the system; and even *supposing that it could be absorbed*, it could not exert any beneficial result. All water is a diuretic, more or less. Mr. PEARSON places very little value on the Buxton waters *per se*; but administered with a certain and most valuable medicine—an alkaloid—which he has prescribed, he has effected several wonderful cures. The lime salts in the water no doubt exert a beneficial influence.

To divert the reader's attention a little, the following anecdote with regard to how waters of one kind or another become celebrated, is given by the writer of *Bubbles from the Brunnens of Nassau*, with regard to the discovery of the far-famed waters of Sclangenbad. It is characteristic of the supposed origin of many similar watering-places, and as such it may amuse, if it does not much edify, the reader:—In the history of the little Duchy of Nassau, says that graceful writer, the discovery of the spring forms a story full of innocence and simplicity. Once upon a time, there was a heifer with which everything in nature seemed to disagree. The more she ate, the thinner she got. The more her mother licked it, the thicker and more staring was her coat. Not a fly in the forest would bite her. Never was she seen to chew the cud; but, hide-bound and

melancholy, her hips seemed to be actually protruding through her skin. What was the matter with her no one knew; what could cure her, no one could divine; in short, neglected by her master and her species, she was, as the faculty would term it, *given over*. In a few weeks, however, she suddenly reappeared among the herd with ribs covered with fat, eyes like a deer, skin as sleek as a mole, breath smelling sweetly of milk, saliva hanging in ringlets from her jaw. Every day seemed to re-establish her health, and the phenomenon was so striking, that the herdsman, having watched her, discovered that regularly every morning she wound her way in secret into the forest, until she reached an unknown spring of water, from which, having refreshed herself, she quietly returned into the valley. A young Nassau lady showed symptoms similar to those of the heifer, and the herdsman recommended the water, which cured her!

GLOVER says justly in his very readable work on mineral waters, that there is a certain mystery connected with the origin and mode of operation of some of them, which no doubt with many is attractive, just as in the extraordinary doctrines of HAHNEMANN and others. Many of these waters, and especially the thermal ones—Buxton, *et cetera*—produce effects in general estimation far beyond what can be accounted for, either by their chemical composition and the power of their *known* ingredients, or by their temperature as shown by the thermometer, in comparison with those of ordinary water baths.

ALKALINE WATERS.—Carbonate and bicarbonate of soda are the characteristic ingredients in such mineral waters. The thermal springs of Teplitz and Ems come under this class, also the Vichy waters, which have long been noted for the cure of stone and gravel; but of late years they have been the subject of discussion among French physicians as to their efficacy in these disorders.

Among the mineral waters in this country which contain carbonate of soda are those of Ilkeston in Derbyshire, near Nottingham, and Malvern in Worcestershire, an analysis of the latter being appended. These waters have only recently been minutely analyzed in the Editor's laboratory:—

The above waters issue from the rock at the rate of

about three gallons a minute, and they have been renowned as highly advantageous as an external application to indurated scrofulous tumors, ulcers, and many eruptive diseases, owing to the trace of iodine, as well as efficacious and beneficial when taken internally, for acidity, dyspepsia, *et cetera*—if so, why not take the active ingredient *per se at home*?

Dr. BOOKER thus apostrophizes the Holy Well—

Ever could I stray
Beside thy stream thou purest spring that flows;
Climb each bold eminence, and daily find
Some object new for wonder—ever gaze
On the wide scene around me, and regale,
When thirst demands, or pleasing taste invites,
At thy clear rill that sparkles at my foot,
And think it luxury.

Chemically it is not *the purest spring that flows*, that of St. Ann being much *purer*. Poetically, however, it may be.

Silicious Waters.—Most mineral waters contain traces of silicic acid, but some hold it in such quantity that the term *silicious* is applied to them. In the boiling springs of Geyser and Reikum in Iceland it amounts to nearly the half of the solid constituents. The action of such water—of course the silica is united to an alkali—will be similar to those of the soda or potassa waters. Annexed are analyses of several of the most important mineral waters on the Continent:—

SEA WATER—*Aqua Marina*.—The waters of the ocean and inland seas are comprised under this head. It is rather a remarkable fact that the Dead Sea differs greatly in its constitution from sea-water, and might, as stated by PEREIRA, to whose excellent work the Editor is indebted for most of the preceding valuable information, be ranked amongst mineral waters.

According to the analysis of MARCET, the water of the Dead Sea contains 24·6 per cent. of fixed matter, and possesses an extraordinary density, 1·211—

	Centesimally represented.

	1000.00000	1000.00

SCHWEITZER also detected iodine and ammonia, and BALARD found iodine in the Mediterranean; and no doubt it contains bromine and other constituents. In fact MALAGUTI detected *silver* in sea-water.

To render such water fit for drinking, it is evident that the greater part of these saline constituents must be removed; and, as TOMLINSON remarks, it has long been a desideratum to enable ships' crews to employ sea-water for different culinary purposes, with the view of removing the necessity of carrying large supplies of fresh water. Almost innumerable are the contrivances invented to meet this end, and, according to the above-cited authority, the most effective is GRANT'S, by which the cooking of victuals and the purifying of water are carried on synchronously. The apparatus is called *the distilling and cooking galley*. The galley contains the fires and vessels necessary for cooking. During the time when the fires are ignited, a portion of the heat is applied to the external part of vessels containing sea-water; the water boils, and steam distils over, leaving, of course, the salts in the still. The steam condenses in a worm, and is nearly pure water, which, of course, is vapid; but the taste may be improved by access to open air and agitation. Where steam-power is used, GRANT'S apparatus affords a ready and effective means of separating fresh-water from salt. PEREIRA says that CLARK'S patent improved pyrohydropneumatic apparatus for easily converting sea-water into fresh is a convenient form of still adapted for sea service. Congelation separates fresh from sea-water. In freezing the pure water only congeals, not the saline ingredients; hence the ice of the polar seas yields fresh water.

Physiological Effects and Uses.—Sea-water taken into the stomach excites thirst, nauseates, and in large doses occasions vomiting and purging. The repeated use of it in moderate doses has been found of service on account of its alterative and resolvent operation in scrofulous affections, especially glandular enlargements and mesenteric diseases. Its topical action is more stimulant than ordinary water. It is used as an embrocation in chronic diseases of the joints. Baths of it are not so exhausting as those of common water. It is a popular opinion, perhaps well founded, that patients are less likely to catch cold after the use of salt than of fresh water.—*Pereira*.

ARTIFICIAL AND AERATED WATERS.—About forty years ago, when the fabrication of mineral and spa waters commenced, a very violent opposition arose with regard to them, especially from the members of the faculty. They were said to be devoid of all the good qualities of the natural ones—to be minus a certain *conditio sine qua non*, in the shape of a *spiritus rectus*, or vital force,

which imparted the medicinal qualities. The Editor has lived to see such statements reversed. Chemistry, the great revealer of hidden treasures, has demonstrated to a certainty what the constituents of the natural waters are; and thus one is now enabled to produce artificial waters quite equal, if not superior to the natural ones. At the Brighton pump-room many artificial waters are prepared imitative of those of Carlsbad, Pyrmont, Vichy, Kreuznach, Ems, Seltzer, and many others, too numerous to detail. Messrs. ELLIS of Ruthin prepare a beautiful imitation of the Seltzer water which, on being analysed by the Editor, yielded exactly the same constituents as the far-famed Bohemian spring. The artificial is certainly more palatable than the natural water, owing probably to the freshness of the carbonic acid infused into it by the admirable apparatus of TYLER, which will be explained further on. To dwell particularly on artificial waters would be tedious and uninteresting to the reader; it is sufficient to state that in their manufacture the salts, in the same proportion as contained in the natural spring, are dissolved in as pure a water as possible, and are then more or less charged with carbonic acid or other gases.

It was PRIESTLEY who, in 1772, proposed to impregnate water direct with carbonic acid, and in 1774 prescriptions for the artificial production of Selters and Pyrmont waters, founded on an accurate analysis of the same, were published by BERGMANN.

Some years ago LIEBIG analysed the Friedrichshaller water, and it is now prepared in large quantities exactly with the salts, *et cetera*, and in the same proportion as given in his results; and if one may judge by the success the imitation has met with, the artificial has almost entirely supplanted the natural beverage. The Editor may here remark, that it is to a certain extent immaterial whether one dissolves carbonate of magnesia, carbonate of lime, sulphate of lime, chloride of sodium, sulphate of soda, *et cetera*, or, on the other hand, chloride of magnesium, chloride of calcium, carbonate of soda, and sulphate of soda, if care be taken that the proportion of the respective bases and acids are strictly in accordance with the figures given by analysis; since they will, in all probability, combine in the same manner as they are associated in the natural spring. The rapid increase and spread of the manufacture of artificial waters, is the best proof that physicians find the medical and therapeutic effects of them are *identical* with those of the natural ones, whilst their *identity* in a physical and chemical point of view can hardly be questioned.

Now that the chemist is able to distinguish the ingredients actually efficacious in a water, a much more active mixture than the native spring can be prepared. To show the extent to which the manufacture of aerated waters has advanced, Messrs. ELLIS and SON, the celebrated manufacturers of soda and other carbonated beverages, inform the Editor, that at Ruthin alone, North Wales, they send out yearly *many thousand gross of effervescing beverages*. So that with other factories at London, Malvern, Liverpool, Manchester, Glasgow, *et cetera*, the trade has within the last few years become an enormous one.

Soda-Water.—This is certainly the principal aerated

water manufactured. How many thousands or millions of bottles of it are drunk annually either alone or mixed with sirups, wines, or spirits? The materials for soda water are carbonate of soda and tartaric acid.

It is a well-known fact that a large portion of the SODA water in general use is simply carbonated water, without the alkali, and as such, is a safe and agreeable beverage; but the physician, or the invalid, or any one who seeks therapeutic and corrective influences of the water, will be greatly disappointed in the use of these fluids, as they are inert, and for such purposes worse than useless. It is difficult to find a person who is not subject to occasional annoyance from acidity. To such an individual a glass of soda-water has been found to impart immediate relief. The carbonic acid appears to produce a peculiar sedative action upon the irritated mucous lining of the stomach, and the alkali neutralizes the excess of acid, and restores the organ to a condition of comfort which few but those who have suffered from the annoyance of heartburn can appreciate. Dr. BENGE JONES, in a treatise upon gout, strongly recommends the use of soda or potassa waters, but laments that the waters so-called in commerce are not alkaline at all; and numerous physicians of eminence have expressed the same complaint.

Some time ago the Editor was greatly pleased in inspecting the admirably conducted establishment of ELLIS at Ruthin, North Wales. Everything was so nice and clean; and, as for the water employed from a deep and splendid well upon the premises, it might be said to be absolutely pure; and it is on this account that he considers the soda, potassa, and other beverages prepared in these works superior to any other in the market. Messrs. SCHWEPPE and others, no doubt, manufacture equally well; but they do not start with *as pure a fluid*. The quantity of soda or potassa in each bottle at Ruthin is twenty-five grains of the bicarbonate of either alkali; and the carbonic acid is equal to about two hundred and fifty or sixty cubic inches, showing how well the gas is compressed. The water from the well only holds *two grains* of solid matter in solution, and *has not a trace of organic matter*; hence it is not liable to alternate or decompose, if kept for any length of time. The apparatus will now be described; and for the following, the Editor is again, as in several instances, indebted to TOMLINSON'S excellent Cyclo-pedia.

An elegant little apparatus has been brought into use within the last few years, patented by M. MATHIEU, as an improvement upon an earlier invention. It is calculated for the preparation of aerated beverages in private houses rather than for sale, since it can yield but a small quantity at a time. There are two oval glass vessels—the larger one placed vertically over the smaller. There is a passage of communication from the one to the other, and in this passage there is a tap for drawing off the aerated liquid. The upper or larger glass is filled with water by removing the cover; and the lower or smaller glass is supplied with the powders. These powders are, as in other cases, of different kinds, according to the sort of beverage to be produced. A small pipe descends from nearly the top of the upper to nearly the bottom

of the lower vessel; a little water descends through this pipe, mixes with the powder, and produces gases; and these gases ascend to the water in the upper vessel. Of course, such gases only as are soluble in water are generated. The gas chiefly used is carbonic acid, of which water will absorb its own bulk, and by pressure can be made to take up another volume. As the gas accumulates in the upper vessel, the pressure increases, and the water is thus enabled to take up its additional supply. The two vessels are generally surrounded with a netting of wire or cane for security. In the simpler forms of the apparatus, nothing further presents itself; but in M. MATHIEU'S improvement there is a refrigerating contrivance. The upper vessel is surrounded by an external shell and sheath, so as to leave an intervening space; and into this may be introduced either ice, or cold water, or freezing mixture.

GAILLARD and DUBOIS' gazogene, or aerated water apparatus, is a much more complicated contrivance. It contains three distinct chambers or vessels—one for the water to be aerated, one for the effervescing powders, and one to contain a small quantity of water which is to act upon the powders. It is necessary to separate all three vessels when the apparatus is to be prepared for use; and this is one cause of its complexity. When all three have been properly supplied, the finger is pressed upon a stud or button at its top. This pressure opens a valve which allows the water in the small upper vessel to descend into the one containing the powders. The gas, thus generated, can only escape from the powder-vessel by descending a small tube which dips into the larger one; and the water with which this larger vessel is nearly filled becomes impregnated with the gas. A second finger-stud governs the valve of a small pipe, which enables the aerated water to flow from the apparatus, which is elegant in construction, but has not the elegance of simplicity.

Mr. MASTER'S aerating machine is similar in principle to MATHIEU'S, though differing in details. The powders are placed in the lower part, and the water in the upper; a little water descends to the powders, and the generating gas ascends. A stud, acted upon by the thumb, draws off the beverage when required.

Messrs. TYLER, HAYWARD and Company's patent double soda-water machine is adapted for bottles, and can make three hundred dozen *per diem*. There are two distinct machines in one frame, which can be worked together or separately. It consists of a condenser divided into two by a partition inside. Each half has an agitator, worked by a wheel. There are two condensing pumps, with regulating taps for admitting aerated water. The pumps are worked by a beam. The beam, by its reciprocating motion, causes the plungers beneath the pumps to ascend and descend in their barrels, forcing at each successive stroke the gas and water together into the condenser. About ten minutes are required to get the charge up, and the bottling then goes on uninterruptedly.

Messrs. TYLER and Son have invented single and double soda-water machines of ingenious construction. Mr. W. Cox of Manchester has patented an apparatus

in which the impregnating gas may be sustained at a pressure sufficient to cause its absorption by the water without the aid of force-pumps. BAKEWELL'S apparatus is another contrivance, applicable to the preparation not only of cooling drinks, but of effervescing draughts also, whether tonic, aperient, diuretic, antacid, or pectic. In short, every aerating apparatus may be said to comprise these two parts—one to produce a gas, and one to mix it with plain water, or water containing carbonates of soda, potassa, magnesia, *et cetera*, or orangeade, lemonade, gingerade, and the like.

ANALYSIS OF WATERS.—*Method of Testing for and Determining Nitrous and Nitric Acids.*—Almost all river waters, and especially the shallow well waters of towns, contain variable quantities of nitrous and nitric acids generally in combination with lime, as nitrite and nitrate of that base. Their constituents have hitherto been generally overlooked by analysts, but on their presence and quantity the chemist may form a more correct idea as to the contamination of the water by organic matter than by any other means. The Editor, therefore, attaches the greatest importance to the determination of these constituents, especially when the water is selected for domestic use.

It has been previously stated that ammonia is one of the principal products of the decomposition of animal matter. This ammonia very speedily becomes oxidized and converted into nitrous acid— NO_2 —which, by longer exposure, is further oxidised into nitric acid— NO_3 . The above-mentioned acids depend for their origin on the presence of organic matter capable of yielding ammonia, and the solvent action of waters upon lead, is almost entirely due to these acids.

Method of Determining the Hardness of Water.—The so-called *hardness* of a water is dependent, as already stated, upon the presence of a certain proportion of the salts of lime and magnesia, which possess the property of decomposing an equivalent quantity of soap, and rendering it useless as a detergent. These salts are bicarbonates of lime and magnesia, and the sulphates of the same basis. The former impart to water its *temporary*, and the latter its *permanent* hardness. The two bicarbonates are decomposed by boiling; the insoluble monocarbonates being deposited, and, mixed with small quantities of the other mineral constituents, form the incrustations which are frequently observed on kettles and boilers in which hard water is employed. In order to determine the temporary and permanent hardness of water, the following method is adopted:—

Into a six ounce stoppered bottle put one thousand grains of water; agitate briskly, and suck out the air by means of a piece of glass tube. This is necessary in order to remove the free carbonic acid, which might interfere with the soap test. Fill the graduated burette with soap test solution, add one measure, and agitate briskly. If no lather is produced, add more, and shake again. Continue adding the soap-test till a permanent lather is produced. Even in moderately hard water a white opalescence appears immediately on adding a few drops of the test, and a white curdy mass will be seen to collect on the surface. Pure soap, such as is used in

making the test solution, is a stearate or palmitate of soda, which is readily soluble in pure water; but when it is added to a water containing salts of lime and magnesia, the soluble soda-soap is decomposed, and an insoluble soap of lime and magnesia produced. The decomposition is represented in the following equation:—

A similar decomposition takes place with soluble salts of magnesia, and hence, when hard waters are used for washing, not a particle of soap will act as a detergent until the whole of the lime and magnesia is removed.

In accurate analysis it is important to make a double determination of the hardness—one before the water is boiled, and another after a portion has been boiled for about six hours. The degree of hardness after boiling represents the hardness due to sulphates and chlorides of the alkaline earth metals, while the difference between the hardness obtained after and before ebullition indicates that which is due to the carbonates of those metals. For example, if a water has a hardness of fourteen degrees before boiling, and of four degrees after, the water is then said to have a temporary hardness of ten degrees, and a permanent hardness of four degrees.

That the determination of the hardness of water is important cannot be denied, since it furnishes a certain guide to the proper association of the acids and bases when one comes to arrange the results of a complete analysis. But until chemists are agreed upon the character of a type-water, its true value cannot be properly appreciated.

Determination of the free Carbonic Acid in Water.

—Water which has been allowed to stand for some hours in an open vessel becomes insipid and mawkish to the taste, or in popular language, it is flat. This is owing to the escape of carbonic acid, which occurs in many spring and well waters. Hence, in giving a correct opinion of the value of a water for dietetic purposes, it is sometimes necessary to determine the number of cubic inches of free carbonic acid in a given measure of the water. This is an operation which ought to be performed at the source, and is best done in the following manner:—A well-stoppered glass bottle holding a gallon is required for the purpose. Put into it two fluid ounces of strong ammonia, and two fluid ounces of a saturated solution of chloride of calcium. If both materials are pure, the mixture will remain perfectly bright. After observing that no milkiness is produced, depress the bottle into the stream or well, and fill it gradually, taking great care not to dip the neck entirely beneath the surface, but only partially, so as to allow space for the air to pass out, while the water is flowing in. This precaution is essentially necessary, since, if the water were to be agitated by the air escaping from the bottle, much of the free carbonic acid would be expelled by the agitation so occasioned, and hence erroneous results would be obtained.

After carefully filling the bottle with the water, it is

to be stoppered and left for three or four days. After that time, the whole of the carbonic acid will have been precipitated in the form of carbonate of lime. This is to be filtered off, dried, and weighed. From the total weight of the precipitate is calculated the quantity of carbonic acid according to the following formula—

$$50 : 22 :: \text{the weight of carbonate of lime} : x$$

The value of x will give the quantity of carbonic acid contained in the water.

Some, however, of this carbonic acid is in combination with lime and magnesia, and it is therefore necessary to determine the quantity, in order to ascertain how much exists in a free state. This requires a separate operation. A gallon of the water is introduced into a large glass flask, and boiled for six hours. The diminution in bulk occasioned by evaporation is made up with pure distilled water. The precipitate produced by boiling is collected on a filter, and the portion adhering to the bottom of the flask is dissolved by a little dilute hydrochloric acid. The precipitate on the filter is dissolved, and the two solutions mixed together. The solution will contain traces of silica, iron, alumina, and phosphate, which may be disregarded; its chief components are carbonate of lime and carbonate of magnesia, which being separately determined, their weight is to be deducted from the weight of the precipitate obtained from the bottle in which the ammonia and chloride of calcium had been used. From the difference may be calculated the quantity of carbonic acid per gallon. One grain by weight measures as nearly as possible two cubic inches. Therefore, if the difference in the weights of the two precipitates amount to a weight of carbonate of lime containing twenty grains of carbonic acid, the water will be proved to contain forty cubic inches of that gas in a free state per gallon.

Determination of the Alkalinity of Water.—By the alkalinity of water is understood the quantity of potassa or soda which may be present in combination with carbonic acid. For ordinary drinking purposes it is quite unnecessary to perform this operation, but when water is used for brewing, dyeing, and starch-making, the presence of the alkaline carbonates is a matter of great consequence. The following method, though by no means perfect, is generally adopted. Two gallons of the water are evaporated in a large platinum dish down to about four fluid ounces. This is filtered from the deposit, colored with tincture of litmus, and then neutralized by a standard solution of sulphuric acid, containing in a hundred cubic centimeters as much acid as will neutralize one grain of alkaline carbonate.

Determination of Chlorine.—Half a gallon of water is evaporated to about four fluid ounces. Dilute nitric acid is then added to dissolve the precipitated carbonates. The whole is transferred to a beaker glass and filterer, the filter being thoroughly washed. To the solution is now poured in a slight excess of nitrate of silver, which throws down all the chlorine as chloride of the metal. The menstruum is now boiled, filtered, and the precipitate well washed with hot distilled water, then dried at 212° , ignited in a porcelain crucible, and weighed—143.5 of chloride of silver contain 35.5 of chlorine.

In determining the chloride of silver, the filter containing it should be completely exsiccated, then ignited very gently in the porcelain crucible; as soon as it ceases to burn, the carbonaceous residue of the filter should be slightly moistened with concentrated nitric acid, and again burned. By repeating this process several times, until all the carbon of the filter is destroyed, any loss of chloride of silver will be avoided; but before weighing, it is well to moisten the residue with hydrochloric acid, and ignite, in order to convert any reduced metal into chloride.

Determination of Sulphuric Acid.—Half a gallon of the water is, as in the preceding instance, evaporated to three or four ounces, and acidified chloride of barium is then to be added, and the whole boiled, and left for twelve or more hours in repose, then filtered, and the sulphate of baryta washed thoroughly and dried. 116.5 of sulphate of baryta represents 40 of sulphuric acid.

Directions for determining in Water the Non-volatile Organic Matter—Silica, Iron, Alumina and Phosphates; Lime and Magnesia.—Evaporate slowly half a gallon of water to about a pint, over a gas flame; then transfer the dish to a sand-bath, and continue the evaporation till the bulk is reduced to about two fluid ounces. Now accurately weigh a clean platinum dish. Scrape the deposit carefully from the bottom of the porcelain basin, and rub off that which cannot be removed by the platinum knife with the middle finger; rinse the whole into the platinum dish, and then evaporate to dryness on a water-bath. Be careful to observe that every particle of the deposit is removed from the porcelain vessel. When the residue is dry place the dish in an air-bath, and heat it for half an hour or an hour at a temperature of 260° .

The object of heating the residue to this temperature is to expel the water of crystallization combined with sulphate of lime, which is almost an invariable constituent of well and river waters. Note down the weight. The difference between the weight of the basin when empty and that of the dish and residue will, of course, represent the actual weight of the residue in half a gallon of the water. The residuum being thoroughly desiccated and weighed, place it on a platinum triangle, over a good gas flame, or the flame of a BERZELIUS lamp, and ignite until the blackening produced by the carbonization of the non-volatile organic matter disappears, and the mineral constituents are white. The time required to produce this change should be carefully noted. If nitrates or nitrites be present, as is invariably the case in waters containing sewage and other animal matters, then gently facilitate combustion of the organic matter, and the residue becomes white in a few moments.

On the other hand, if the water be contaminated with organic matter which has undergone but little decomposition, and especially if urine be present, the carbonaceous residue will require very lengthened ignition in order to consume the carbon. If it be necessary to heat to redness for any length of time, some of the carbonic acid in combination with lime and magnesia will be expelled, and consequently the loss of weight occasioned by the ignition would not correctly represent the actual quantity of organic

matter. It is, therefore, necessary to *recarbonate* the lime and magnesia. This is done by moistening the residue with a few drops of a strong solution of carbonate of ammonia, and again drying it at 260° till it ceases to lose weight. The dish being now weighed again, and the weight noted, the difference will represent the quantity of non-volatile organic matter present with the mineral constituents. By the continued ignition which is necessary to burn the organic matter, the *silica* is rendered *perfectly insoluble*. To the residue in the platinum dish is now added a fluid ounce of water, and, drop by drop, strong hydrochloric acid—about one in two fluid drachms—until effervescence ceases. Particular attention should be paid to the odor of the gas evolved; if it smells of sulphide of hydrogen, this will be a further indication of the contamination of the water by *animal refuse*.

After the effervescence has ceased, the dish should be gently heated on a water-bath and the solution filtered. The silica left on the filter should be washed well with hot distilled water, till a drop of the washings, evaporated on a platinum knife, no longer leaves a trace of residue. The filter containing the silica is dried, ignited in a weighed platinum crucible until the whole of the carbon is consumed, and then weighed. The filtrate from the silicic acid, after the washings have been added, is to be neutralized and made slightly alkaline with ammonia. The iron, alumina, and phosphates of the alkaline earths are precipitated, then filtered and washed with the same precautions as given in the determination of the silica, and when dried, weighed. As the iron, alumina, and earthy phosphates occur in water in very small quantity, rarely exceeding together a grain per gallon, it is for general purposes quite unnecessary to separate them. The precipitate produced by ammonia is usually recorded as *iron, alumina, phosphates*. After the precipitate is completely affused, and the washings are added to the filtrate, the lime is next to be thrown down, and this is done by adding oxalate of ammonia in excess; allow the whole to stand till the supernatant fluid becomes bright. Add the washings to the filtrate.

The precipitate is to be dried, ignited, and weighed. By ignition the oxalate of lime is converted into carbonate, and is weighed as such. The following decomposition occurs during ignition:—

As a portion of the carbonic acid of the carbonate of lime might be driven off during the heating, it is advisable to moisten the residue in the crucible with strong carbonate of ammonia, once or twice igniting after each addition, and taking the weight when it becomes constant. Fifty of carbonate of lime represent twenty-eight of lime. The washings being evaporated and added to the filtrate, about half a fluid ounce of a solution of phosphate of soda is added, and the menstruum allowed to repose for twenty-four hours in a moderately warm place. The magnesia is thus precipitated as phosphate of magnesia and ammonia— $2\text{MgO}, \text{NH}_4\text{O}, \text{PO}_5$. This salt must be well washed with dilute ammonia—one part alkali to six of water—dried, ignited,

and weighed. By burning, the precipitate is converted into pyrophosphate of magnesia— 2MgO PO_5 —from which the quantity of magnesia is ascertained. One hundred and twelve of the pyrophosphate contain forty of magnesia.

Determination of the Alkalies.—The determination of the alkaline salts in water is generally omitted in ordinary analysis; but it must be acknowledged that when water is required for certain purposes, as for instance, for brewing, it is very important to determine not only the quantity of potassium and sodium present, but especially the form in which they occur, whether as chlorides or as carbonates. For brewing purposes it is usually considered that waters containing sulphate of lime are best suited for the manufacture of pale ales, since beers made with selenitic waters are paler than those made from water free from gypsum; but notwithstanding the presence of sulphate of lime, if potassium and sodium be there as carbonates, it is impossible to obtain a pale infusion of malt, owing to the alkaline carbonates extracting certain constituents which are not soluble in water free from alkalies. The following is the best method of determining the alkalies. Half a gallon or a gallon of water is evaporated to dryness in a porcelain dish in the usual manner. The residue is dissolved in hydrochloric acid, and evaporated on a water-bath to dryness. The soluble constituents are then extracted by water, and to the aqueous solution is added an excess of baryta water. After the precipitate has subsided, the solution is filtered, and to it is added a *very slight* excess of *pure* carbonate of ammonia. The excess of baryta thus precipitated is filtered off, and the solution which now contains only the alkalies, as chlorides, is evaporated to dryness in a weighed platinum dish, to determine the quantity of mixed chlorides of potassium and sodium. The weight being noted, the chlorides have now to be separated. This is accomplished by dissolving in water, adding excess of bichloride of platinum, and evaporating to dryness on a water-bath. The mixed platinum salts are now treated with alcohol and ether, filtered and washed with a mixture of ether and alcohol till the washings come through perfectly colorless. The precipitate of bichloride of platinum is then weighed, and the quantity of chloride of potassium it represents is calculated. This is deducted from the weight of mixed chlorides, the actual quantities of potassium and sodium calculated.

Having now determined the actual proportions of all the ordinary acids and bases present in the water, one has then to associate the acids and bases together as salts, in the form in which they probably existed in the water previous to analysis.

The association of the acids and bases is founded entirely on arbitrary rules, the usual plan being to unite them in the order of their respective affinities—the strongest acids with the strongest bases. But this is obviously an incorrect method, since it is often found that two chemists analyzing the same water will give entirely different forms of analysis, although they may both have found the same proportions of the respective acids and bases; the one will associate all the sulphuric acid with potassa and soda, the other may place it with

lime, and regard the alkaline bases not as sulphates but as carbonates. Now, as before shown, it is a question of the greatest importance, when water is required for special purposes, to determine not only the proportions of acids and bases present, but the form in which they are associated. In order to do this properly the analyst must have regard—1st, To the geological characters of the source of the water; 2d, to the nature of the country through which it flows; 3d, to the contaminations from sewers and manufactories to which the water is exposed.

Rain-water, it is to be presumed, cannot differ materially in the nature and quantity of its impurities, but yet it has been shown that one rarely finds two river waters of precisely the same composition. In the water of the Dee, the analyst finds only about four grains of mineral matter, because the rocky soil over which it flows is soluble only to a slight extent in native water. The water of the Trent flows over a soil abounding in gypsum, and consequently the water is very hard, while in the water of the Thames, which flows through a line of country composed essentially of chalk, the prevailing constituent is bicarbonate of lime. The presence of a superabundance of earthy salts in water, exercises an influence of some importance in many of the industrial works of the kingdom, and especially in brewing. Paradoxical as it may seem, it is now an ascertained fact, that the hardest waters, that is, such as contain most earthy salts in solution, have the greatest extractive power for the brewer; and further, that the chemical changes that take place between certain constituents of the malt and those salts, serve in the case of ale brewing to fine the beverage in the natural way, without the aid of disgusting and corrupt *stuffs* employed for this purpose very frequently.

A glance at the composition of the waters which are used by ALLSOPP and BASS, the Great Burton brewers, and by TETLEY, of Leeds, *et cetera*, gives at once the clue to the superior excellence of the manufactures of these parties over ales made from such liquids as the *Liverpool Pike*, which is not only devoid of earthy salts in the requisite quantity, but contains an amount of animal and vegetal matter in such a state of fermentation, that the action is engrafted on the glucose, and proceeds in the tun collaterally with the alcoholic fermentation, which it ultimately modifies into the lactic and acid fermentation long after the natural ferment—the gluten of the malt—has been thrown off:—

The quantity of calcareous salts in the above waters is a proof of the beneficial action of lime in the preparation of the best malt liquors.

ELECTRICAL PROPERTIES.—This article on water
VOL. II.

would be incomplete without making some allusion to its electrical properties, which are not only turned to useful account in the numerous and increasing applications of electricity, but also perform an important part in the great phenomena of nature. It would be improper, perhaps, to particularize under this head the hydro-electric machine, because although in that apparatus very large quantities of electricity are generated by the issue of steam through narrow apertures, the effect has been attributed by FARADAY to mere friction, and therefore exhibits no new property of the water itself. It is in the electricity which it generates by contact with oxidizable metals in the galvanic battery, and in the variable conducting power of the liquid according to its greater or less admixture with different acids and salts, that water assumes its chief importance in electro-chemical action. In the working of the battery, for example, it is the decomposition of the water which accompanies the oxidation of the zinc or other positive metal, and not the action of the acid or salt superadded, that really produces the electricity. This was demonstrated by KOHLRAUSCH, who showed that the electric tension was the same at the poles of two similar batteries, one of which was charged with distilled water and the other with a mixture of water and sulphuric acid. The remarkable effect of certain acids and salts in increasing the energy of the current, is chiefly due to the peculiar property which they possess of increasing the conducting power of the liquid. The following table exhibits this property in a very striking light:—

	Conducting power
Distilled water,.....	0.0125
Do. with 1-20,000 of nitric acid,.....	0.075
Sulphate of copper, saturated solution,.....	5.42
Sulphate of zinc, do. 	5.77
Nitrate of copper, do. 	8.99
Chloride of sodium, do. 	31.52
Sulphuric acid diluted with eleven measures of distilled water,.....	88.68
Nitric acid, specific gravity 1.31,.....	93.77

From which it appears, that the addition of only one twenty-thousandth part of nitric acid to distilled water increases its conducting power about sixfold, and that one measure of sulphuric acid, added to eleven of distilled water, increases its conducting power seven thousand times. Distilled or absolutely pure water is therefore a very bad conductor of electricity; but it has been shown that water of this extreme purity is not to be found in nature; that even rain-water is more or less impregnated with certain foreign ingredients, and that the waters of rivers and wells vary immensely in the amount and character of their saline constituents. It is therefore that, in rainy weather, the moisture of the atmosphere, acting the part of a conductor, destroys the insulation of the telegraph wires, and obstructs the working of the instrument; it is therefore that the earth, and still better, the briny waters of the ocean, not only transmit natural currents, but submit themselves as willing agents to the purposes of telegraphic communication; and lastly, it is to the moisture of the atmosphere, floating in clouds charged with an opposite electricity to that of the earth, that the grand phenomena of the thunderstorm chiefly owe their existence.

WINE.—*Vin*, French; *Wein*, German; *Win*, Anglo-Saxon; *Wyn*, Dutch; *Vino*, Spanish and Italian; *Vinho*, Portuguese; *Vinum*, Latin; *Oinos*, *Ovos*, Greek. —All these denominations were probably derived from *Oinos*, with the digamma prefixed, answering to F or V in English, as *Voinos* and thence the Latin *Vinum*. The Hebrew term for wine in general, is *Yayin*, but if medicated or, in other words, made more potent by the admixture of herbs or drugs, it was denominated *Shekhar* or *Strong Drink*, in common with other fermented liquids. The Greek name being the parent of the Latin, confirms the tradition that wine came into the more Western parts of Europe from Greece by way of Italy, and from Asia into Greece.

When man was driven from that peaceful asylum originally assigned to him by his Creator, and condemned to earn his bread by the labor of his hands, his attention was no doubt powerfully exerted in procuring the necessaries of life; such as food, clothing, and habitation. As a cultivator of the earth, he must have been constantly employed, and, as his occupation varied with the seasons, his mind was continually disciplined on contrivances to diminish and sweeten his toil. His activity, when thus excited, soon extended its influence to every department of life, and having procured its necessaries, he was doubtless early led to task his ingenuity in the attainments of its luxuries. Among these, the preservation of fruit and their juices, however rudely practised, might have led to the use of inebriating drink—a beverage which was discovered by some of the most savage nations, and is deemed a luxury by the almost universal testimony of mankind.

Wine, when an uncompounded word, signifies the fermented juice of the grape only; but when compounded, it is applied as a general term to the fermented product of other fruits in conjunction with the name of those fruits, tendrils, stems, leaves, or similar substances from which it is made, as gooseberry-wine, ginger wine, and all the varieties denominated *domestic* wines.

Wine of the grape is divided into dry and sweet, and under one or the other of these great divisions every variety is included. The characteristics and causes of each of these divisions will be fully explained.

The juice of the grape, which is usually called *must*, is known to ferment *per se* at 70°, which proves that wine was very early known, particularly in hot climates, where drink is so much required to allay thirst; and this is a further sign that the vinous fermentation was familiar long anterior to the deluge.

Carrying this idea still further towards the Creation, MILTON seems to have entertained the opinion that the fruit of which ADAM and EVE had eaten—

— whose mortal taste
Brought death into the world, and all our woe,

was of an intoxicating nature, when he says:—

Soon as the force of that fallacious fruit,
That with exhilarating vapor bland,
About their spirits had played, and inmost powers
Made err, was now exhaled.

Wine is the oldest fermented liquor, its invention being ascribed to NOAH in the traditions of the Jews

almost immediately after the deluge. The Greeks with their fabled DIONYSUS from Egypt, originally from India, threw no light upon the discoverer; but if they learned the art of making wine from the Egyptians, that liquid may be thus traced up to the days of MOSES. HERODOTUS reports that there was no wine made in Egypt, a singular error, when Marcotic and Tæniotic wines were notorious. The wine of Merœ called *indomitum* by LUCAN was far-famed. The writings of MOSES show that the kings of Egypt drank wine, as all who have perused them will not fail to recollect in reading the story of JOSEPH and the chief butler of PHARAOH. The ruined temples of Thebes also display the emblems of the vintage in bas-relief, and figures of men pressing grapes with their hands, the must flowing into goblets emblematic of the wine-press. Some have used this as an argument against fermented wine; but must unfermented, would not keep from decomposition for many hours, even in the Eastern land of miracles; nor would the simple juice have intoxicated NOAH, because to occasion ebriety fermentation is absolutely necessary, as in all other alcoholic liquors.

Next in antiquity to the volume of the Jewish faith are the works of HOMER and HESIOD, who lived so near together in point of time, that even concluding HOMER to have flourished in the tenth century before CHRIST or about the reign of SOLOMON, the difference so much discussed by the learned is of no moment in a scientific sense. HOMER mentions the names of several kinds of wine, and alludes to their potency.

The frequent allusion to wine, the praises bestowed upon it, the flowing goblets, the luxurious banquets as described by the great Grecian poet one thousand years before the Christian era, exhibit its value and his attachment to the comforts of the table and to jovial society.

HORACE was of this opinion when he says—

Homer, in praise of the profuse,
No doubt loved well the balmy juice.

The wines referred to required twenty parts of water to make them potable, as in the case of the Maronean ones. Poets are not to be literally trusted; and in the present case, as the object of HOMER was to intoxicate the giant POLYPHEMUS through his hero ULYSSES, full latitude must be given for poetical fiction, which can seldom be quoted in reference to the exact sciences. This Maronean wine was made from vineyards on the side of Ismarus, a hill of Thrace, by MARON a priest of the Sun. The circumstance of the Greeks mixing water with their wine, might after all mean no more than it does in France at the present time, where water is often mingled with common wines of the country by no means remarkable for their strength. Thus the wine of Scyathos is said to have been used with half its bulk of water. The wines most in repute with the Greeks were, in the first place, the wines of Chio or Chios, which, with the Thasian, were ranked among the superior growths. Lesbos was also celebrated for its wines. Many of the Greek islands were distinguished for wines of delicacy and flavor, for the most part rich and sweet. The Ariusian wine of Chio was in high esteem as a luscious

product of one of the vineyards of the island. The Pannonian was celebrated for its healing qualities. This wine was red, from a vineyard in Lesbos. The wines of Rhodes, Crete, and the Clazomenian from the shores of Ionia, were much valued, and often taken with an admixture of sea-water, a singular custom, thought to impart smoothness to the wine. The quantity thus mingled was very small, and was always boiled before it was mingled with the wine. The Greeks classed their wines, as in modern times, into sweet and dry, but had an intermediate species. They seem to have preferred the thick sweet wines to all others, that species, for example, which the moderns denominate malmsey, differing little perhaps from the modern wine of Cyprus, or the malvasia of the Morea. Some of these wines possessed what is now called the bouquet. As soon as they were opened to the air, the perfume was immediately perceived, but this might have arisen from the infusion of odorous substances at the time of fermentation, a practice then common. Sappian wine was one of those celebrated for its odor on being uncorked. This odor, it is pretty clear, did not arise, as it does in the pure wines of France in modern times, from the natural perfume after fermentation, but from the addition of odorous substances. Port and the strong Anglo-medicated wines at present, possess no bouquet from its being destroyed by the admixture of alcohol with them artificially, rendering them heavy and dull. The wines of Bordeaux, Champagne, and Burgundy, on the other hand, have the perfume in a high degree from nature.

The wine of Chio, called the Phanean, was celebrated among the Romans, who imported both that and the wine of Argitis. The wine of Mende in Thrace was a white wine of no great strength. The wines of Zante speedily intoxicated; and those of the other Greek islands, as well as of Lydia, Phœnicia, and Cilicia on the mainland, were of good quality, producing growths the mere names of which it would be superfluous to record.

Rome, as she learned the other arts from Greece, acquired also that of making wine, as soon as she extended her power beyond the limits of her home empire. In the days of HOMER milk was substituted in the sacrifices in place of wine, because of its scarcity at Rome. The wine first made seems to have been from the grape grown in the Campania Felix. The most celebrated sites for the vine were near Naples, on the sides and at the foot of Vesuvius, now covered with the lava and ashes of that celebrated volcano; a spot in which Bacchus was said to have delighted in consequence of its rare fertility and excellent adaptation for the vine culture. The sea washes the limits of this beautiful vine-climate in one direction, and in the other delightful hills, named the Falernian, Surrentine, Massic, Gaurean, and others, arose with the choicest aspect and the most propitious slopes from the low country, giving names to the products since wedded to immortal verse. Thus the Falernian, Surrentine, Cæcuban, Setine, and other wines of the vicinity, were named from their native hills. One or two of the more celebrated writers left passages in their works which enable us to give a guess at the nature of some of the wines in use among the

Romans, whether the growths of Greece or Italy. It is certain from these that, except in the sweet wines of the South of Europe at present, no great similarity could have existed between the ancient wines and those most prized by the moderns. The writings of ATHENÆUS and PLINY give a tolerable account of the treatment of the vine under cultivation, but we learn little from them in relation to the constituent parts, flavor, or qualities of the produce. The same remark will hold good in relation to the extant works of VARRO, CATO, COLUMELLA, and PALLADIUS. In short, no source remains from which any tolerable approximation can take place as to a knowledge of quality and flavor. It is well known on the other hand that the Campanian vine once enriched a considerable territory of great fertility, and that a number of large towns which have now disappeared, once adorned that favored spot. The more famous wine was the Falernian, which some suppose to have been made on the present Monte Barbaro. The Cæcuban, a sweet wine, was made on the palmus lands of Amycle. The Falernian was of three kinds, the dry, sweet, and weak. A celebrated vintage called the Opimian, from the name of the consul that year, L. OPIMIUS NEPOS, took place in U.C. 632, the wines of which bore a great price a century afterwards. The Falernian required nine or ten years to ripen, and when aged was bitter. Some have imagined it was a dark red wine, others that it was white. The Surrentine wine was durable, and generally taken out of cups of the same name. The Massic came from Sinuessa; Trifoline from a hill near Naples; Tarentine from Mount Aulon, near Tarentum; Alban from a hill near Rome; Mamertine from Sicily, near Messina; Cereton from Etruria; Signian from Latium; and Massican from the Abruzzo. The vicinity of Rome also produced the Nomentan, Sabine, and Venafran wines. The north of Italy produced no wines of note. Spain sent the wines of Tarragona to Rome, and France those of Narbonne, Marseilles, and Vienne; but these were said to flavor too much of the smoke of the *fumarium*, or else of pitch.

The Romans suffered their vines to grow high and weakened the must. How the fermentation was managed nowhere appears. The wines were placed in a smoky receptacle to ripen, the object being the same in ancient as in modern times, to assure maturity. The Carthaginian MAGO, who wrote five hundred and fifty years before CHRIST, says, that to make the best wine, that of the sweet or luscious species, the bunches of grapes were gathered when shrivelled by the sun's heat, the bad fruit picked out, and they then were placed upon a frame of open-work covered with reeds, exposed to the sun by day, but sheltered from the dew at night. When they were sufficiently shrivelled they were thrown into a cask and trodden, and thus the first must was made. When drained, they were submitted to the wine-press for the first wine. They were then trodden a second time, and cold must added to the pressing. This second wine was placed in a pitched cask, to prevent it from becoming acid. After it had remained for twenty days in this state it was racked into another vessel, closed up from the air, and covered with a skin.

Such was the ancient mode of making sweet wines of the luscious malmsey species. For the wines in general, the fruit was gathered at intervals as it ripened, and carried to the press in baskets. The must was received in a stone or plastered cistern, and the fermentation was completed as quickly as possible. The process, there is reason to believe, was not very different from that hereafter described. In certain cases the fermentation appears to have been unnecessarily prolonged, and a part of the must that flowed from the grapes by their own pressure was reserved in a separate vessel and set aside, as it is the custom to do now in making Tokay-Ausbruch in Hungary. This must, the most valued, was often stored by itself. Sometimes it was plunged, when in a state of fermentation, into deep water, being previously hermetically sealed. Weak must was often boiled down, so that much of the aqueous portion evaporated, and it was denominated according to the quantity of the portion unevaporated. If two-thirds were left, it was called *calenum*; if only one-third, *sapa*. This was evidently copied from the Greeks, and is still practised, being called in Italy *vino cotto*, and in France *vins cuits*.

The custom of adding sea-water to wine is said to have been discovered by accident. The water was boiled down to a third part, but the quantity used differed according to the nature of the wine. The act of perfuming the wine must have ruined its delicacy; pitch, rosin, cassia, myrrh, saffron, and cypress leaves were, one or the other or several of them, thus infused. The true principles of fermentation were evidently unknown to the ancients, who had not the advantage of modern chemistry. It was the same with the causes of the difference between dry and sweet wines. There was no deficiency in the attention paid to the vines, except that they were permitted to weaken themselves by too luxuriant a growth; this in consequence tended to aid acetous fermentation. In aspect, soil, grafting, and training, all seems to have been well known in ancient times; the Greeks understanding this point better than the Romans. The Aminean grape was the species most cultivated for wine, at least in the Campania Felix, but it cannot be identified with any modern species. October was the vintage month.

The treatment of the ancient wine after the first fermentation included a further progress in the vat, and it was then placed in earthen vessels, hermetically sealed, denominated *amphoræ*, each of which held 6·7827 English gallons, or in other vessels of a different capacity, as the *urna*, which held just half the quantity of the amphora. If an inferior wine, or one designed to be carried to a distance, it was placed in pitched skins—the bottles of the New Testament. When designed for the amphora and cellar, after being exposed to the smoke of the *fumarium*, it had the year of the vintage or the consular year marked upon it, and was set in the ground. Under this treatment in the *fumarium* and elsewhere, some of the wines grew so thick that they could not be drunk until they were dissolved in water. That sometimes the wine tasted of the smoke is not matter of wonder. It is well known that Madeira ripens rapidly if the bottles are plunged into a hotbed or into stable dung. The amphoræ were

vessels without bases, shaped as in Fig. 615, and made of pottery clay. The consulship of the famed Opimian year is marked on some of the existing amphoræ in the way thus exhibited—L. O. NEPOS, U.C. 632. The wines of the ancients were thus different in quality from those of modern times, and could only have been relished by long habit.

The different varieties which have been transmitted by name in Italy, Gaul, and the East are reckoned at a hundred kinds, rough, soft, and sweet. That the wines of the ancients were more durable from this after-management than from any knowledge they possessed of their chemical combinations when treated scientifically according to their nature, and unmingled with substances foreign to them, is evident upon a due consideration of the subject.

Regarding the wines of Asia Minor, little is known in respect to the treatment. Some kinds were kept in the *fumarium* until they became as hard as salt, and it was necessary to dissolve them too in water before they were drunk. The prices they bore, considering their age, were not extravagant; those more than a century and a half old costing less than seven shillings the English quart. In Rome the quantity of wine consumed was considerable. The servants of CATO were allowed about a pint and a half per day. The stocks of the more precious wines kept by the opulent were surprisingly large. Of the best and dearest Greek wine, that of Chio, HORTENSIVS left ten thousand casks at his decease. The celebrated MÆCENAS introduced a rare wine of his own, called *mæcenatianum*. Of the common wine made in Italy, too, the produce was large, being in one recorded case no less than two thousand one hundred and fifty gallons per acre, or eight *culei* on the jugerum or twenty-eight thousand eight hundred square feet. In these computations, however, there is much uncertainty.

Wine was drunk in Rome out of murrhine cups when the eternal city was in its greatest height of luxury and pride. What this substance was is unknown, but it appears to have come from Egypt or the East, and to have possessed an inherent perfume; many dissertations have been written upon its nature, all alike unsatisfactory.

Among names of ancient wines, is that of Helbon or wine of Tyre, called by the Greeks *kalibonion*, and alluded to by the prophet EZEKIEL—the name meaning sweet or fat; it was made near Damascus, originally by the Persians. This wine was common in England in the reign of RICHARD III., being imported in Venetian vessels. The wine of Lebanon in HOSEA, is praised for its perfume. But the different conjectures regarding the nature of ancient wines, built upon no satisfactory data, cannot, any more than their names, be of any real moment, however amusing to the scholar. It may be observed, however, that a marked distinction anciently existed between pure wine, and that which

Fig. 615.

was perfumed or medicated, as with certain wines imported into England, brandy is added for the same purpose, particularly to port wine. The Jews have preserved this distinction in scripture, by using the term *mixed* or *strong wine*; thus—In the hand of the Lord is a cup, and the wine is red; it is *full of mixture*; and he poureth out of the same; but the dregs thereof, all the wicked of the earth shall wring them out and drink them.

Leaving a subject so much of which must be conjectural, the wine of the present time, naturally the most important, comes to be considered, together with the processes adopted by the moderns in its manufacture. The variety of the plant which produces it, and the nature of the soils in which the best grape is matured, are subjects copiously treated of both by French and Spanish writers. In the catalogue of the national collection of vines at the Luxembourg in Paris, there are five hundred and seventy varieties, classed black oval, black round, white oval, white round, grey and violet oval, and grey and violet round. CHAPTAL collected fourteen hundred sorts, and CLEMENTE states that two hundred and fifty species exist in Andalusia alone. The treatment of the vine and the entire culture of the plant belong to the rural economy of the wine-producing countries. To enter largely upon this subject would be out of place here; still the following on the kind of soil best adapted for the grape, and on the best description of grapes to employ, will interest and instruct the reader.

The wine-producing countries in the Northern hemisphere are included between the parallels of 33° and 51° North; but this rule is limited by local circumstances, probably by the line of the biting North-east winds, which keep back the vine in spring. An oblique line drawn a little north of Coblenz, concave to the North, and continued to the mouth of the Vilaine, in 47° 25' North, will nearly define the vine limit. Wine once made in good quality at Estampes and Beauvais, so as to be celebrated, cannot be made there now. Thus it was once made too in the counties of England South of Cambridgeshire. Wine in 1553 was made of the muscat grape at Mâcon in Burgundy, where it cannot now be made at all. In Asia no good wine is made South of latitude 33° North, in Persia and Shiraz. In regard to the Southern hemisphere, except a little sweet wine from the Constantia vineyards at the Cape of Good Hope, none of any mark is yet produced, though much of an inferior quality is made. With the wine-producing countries of the North the world is too familiar to need the exact enumeration.

Keeping in view wines of the first and second class in excellence, nearly all which lay claim to the greatest delicacy and purity are produced in France, where science and long experience have been brought to bear upon their management. In a first-class wine there must be no mixture of any foreign matter whatever. The fermentation must be natural, and no extraneous substance introduced, not even brandy. Nothing must be allowed to prevent the development of the perfect character of the particular species expected—lightness, freshness, a rich odor conferred by nature, such as are found in Romanée-Conti, Chambertin, Vin du

Roi, or Hermitage of the first class, because of such wines only can the term *pure wine* be understood, or a standard be found by which the first-class can be established, and the test be fixed for the inferior kinds. France, Spain, Germany, Italy, Portugal, Hungary, Greece, and Sicily are the principal wine countries of Europe. Tolerable wine has also been made in the extreme South of the Russian dominions.

Passing over the vine culture, the best sites, the diseases of the vine, the training, and the incessant and laborious calling of the vine-dresser, all belonging, as before observed, to rural economy; and therefore only observing that the practice of grafting is pretty general—it may be added that some vines will bear well for a century and a half. There have been examples of three centuries, while others will not be productive for more than forty years.

The extent of the vineyards that produce the finer wines is well known to be very limited. The differences of soil and treatment do not appear sufficient to account for this fact. Although the best vines are grown on a calcareous soil, as on the chalk hills of Champagne and the albarizas of Xeres, of which carbonate of lime forms two-thirds, and in three-fourths of the more celebrated vineyards this is the case, though the necessity of such a description of soil has been denied.

In the vineyards of Andalusia, while some of the above soils contain even seventy per cent. of carbonate of lime, the remainder is a compound chiefly alumina, with a very small portion of silica, and sometimes a little magnesia. In certain spots the soil is almost pure carbonate of lime. This kind of earth absorbs every particle of moisture which falls upon it, and never cracks nor opens in the hottest summers. The albarizas are a series of calcareous hills. The best Spanish wines produced on such a soil, exhibit its virtues very strikingly in the fineness and durability of the product, and militate against the opinion expressed in some districts, that if the soil be porous, light, and free, the presence of lime is of little moment. The fences of the vineyards on the albarizas consist of the prickly pear. Adjoining the albarizas, or chalky soils, come the arenas, or sands; but these are intermingled, more or less, with calcareous particles. About Malaga, where the surface of the country is extremely rugged, the soil consists of limestone, intermixed with slaty schist, over which the rich raisins for export are produced. In the South of France, in Rousillon, the soil resembles that of Malaga, particularly near Perpignan, being slaty schist, or gravel, interspersed with calcareous matter. In some places where the soil is not six inches thick, a hole is bored in the loose rock with an iron bar, in depth about a foot, into which the plant is thrust, among the stony and arid ground. In Burgundy the soil varies much. At Chambertin it is a brown loam, full of gravel, and friable. This gravel consists of small pieces of broken limestone, in some places; in others, of marl with small shells—while, in another place, the vines grow in pure clay, but still with traces of lime in some form. The champagne district, in like manner, is almost wholly calcareous, at least where the best wines are made. Thus the famous sillery is produced from vineyards on chalk,

with an Eastern exposure. At Ay, on the Marne, on both sides of the river, the hills are chalk, and the soil often supported by terraces. *By the river of Marne, and on the hills of Rheims are the celebrated localities*—proverbially so. The chalk, whether it lie deep or superficial, produces the same effect in respect to dry wine of superior quality, agreeably to its treatment and the aspect of the vineyard. The hermitage wine has been cited in proof of the goodness of wine grown on the debris of granite.

Wines of the finest quality are undoubtedly grown upon soils where lime is not immediately visible. Sands in the vicinity of Bordeaux, and granitic soils near the Rhone, flinty and argillaceous earths, are found to produce excellent wine. But hermitage, for example, although produced from vines grown among fragments of granite, is no doubt affected favorably from the calcareous soil hard by, having portions intermingled with them; nor can it be any exception to the fact as respects the finer dry wines, that their superiority is due to their connection with calcareous matter. Sweet wines are produced in almost every kind of soil. Dry wines produced on schist, for example, are poor, compared to those the fruit of which is grown on chalk land; while the sweet wines, such as those of Malaga, are good on that description of soil. The Rivesaltes, a sweet wine of France, is produced on granitic land upon which lies a stratum of pebbles, while the dry wines of the same land which produces those celebrated growths, are sufficiently mediocre. At Ay, where the finest champagne is made, the soil lies upon chalk in some places from ten to fifteen feet thick; but the superincumbent earth is full of pieces of chalk, the surface only being argillaceous; and where most so, causing some difference in the quality of the wine. Very little manure is applied to the vines that produce the best and finest wines. In argillaceous soils the roots of the vines are found not to branch off in a desirable manner; and the facility with which the soil retains the water, causes a degree of humidity prejudicial to the bud. Volcanic soils, on the other hand, give excellent wines, particularly when they are of very ancient date, and rival those the fruit of which is grown on calcareous strata; generally, too, possessing a flavor peculiar to themselves. In all cases the soil must be light, friable, porous, so that water shall not lodge around the plant. The exposition may vary. *Bacchus loves the hills* is an old, but not an unexceptionable adage, as gravelly plains may produce good wines. Sometimes, according to the nature of the country, an Eastern aspect is best; at others a Southern, and even a Northern has yielded excellent wine; much in such a case depending upon the latitude and the more obnoxious winds, as well as the atmospheric temperature. It is remarked, however, that good wine is rarely produced in narrow valleys, especially if a river flow through them.

It will thus be perceived that the nature of the soil for the dry and finest wines must be calcareous, even to pure chalk; in all events it must be sufficiently so to influence the vine most essentially during its growth; and that for sweet and luscious wines, the nature of the soil is of far less moment, such wines being grown

on every kind of soil, except that which produces the most valuable and rare dry growths. In the English colonies, and in the United States of America, not long ago covered with primeval forests, the soil, enriched by the autumnal spoils of ages, is too good for the vine, the fruit of which, for making good wine, differs so much from the character of fruit in general, when intended for the table.

The grapes are various that give out the more precious must. In Rousillon in France, the best wines are from the carignan, grenache, and mataro grape. The celebrated Rivesaltes wine is principally from the white macabeo, the muscat, and grenache blanche; the hermitage comes from the scyras or ciras grape, the roussette, and the marsan. The pineau blanche and pineau noir before mentioned produce the celebrated Clos Vougeot wine in Burgundy. In the Bordeaux wine district, the Graves, Barsac, and Sauterne, come from the white sauvignon, the semillon, the rochelin, blanc-doux, and primeras—all three white—and the black muscade. The best Spanish wines are the produce of the pedro ximenes grape, both at Malaga and Xeres. At Malaga and Grenada one half the plants are of this species; at Xeres, one-eighth; at Motril, four-fifths; and at Paxarete, one-fourth. The grape, giving fine wine in the North, may be productive of wine of very moderate merit in the South. In consequence every country, and even district of the same country, differs in the variety of the fruit prepared. This arises naturally from the circumstances of the temperature and soil affecting one species more than another, for which it may have less affinity. The growths are often mixed. Thus the marsan grape of itself gives a sweet wine, and the rousanne or roussette a dry, therefore they are mixed to prepare the white hermitage, for example. In Burgundy the black pineau is much used, as well as the chandenev. In champagne the norien and pineau prevail, with some of the gamet and gibaudot. The black morillon, and the magdelaine, and the meunier, are early bearing species. The chasselas, supposed to have come from Cyprus, the cioutat or black grape of Corinth, the muscat noir, isabelle, verdet, and black muscade, the carbenet, violet, and corinth in France, the Uva del Rey, the mollar, the listan of Xeres, the larga and doradillo, with the moscatel gordo, are used in different proportions in some places in Spain, but one kind rarely or never alone. To enumerate and describe the five hundred and seventy species in the garden of the Luxembourg in France, could not enable a cultivator to discriminate what species would be best to adopt, so much depending upon site, climate, and annual temperature. The grenache blanche, for example, is only used in the district of Collioure in France. The Hungarian varieties also are numerous; but site and experience can alone determine, as elsewhere, the species most in accordance with the views of the cultivator in producing the best wine.

By a remarkable peculiarity, nature, and habit of the vine, it adapts itself to those parts of the country which are least fitted for the cultivation of the cerealia. Those vines which bear the best fruit for the finest dry wines, invariably grow on soils which would be unproductive

with respect to the food crops. Gravel, sand, volcanic debris, flint, and such like soils, are favorable to the growth of the vine, whilst rich, deep, warm, fat earth, and all rich lands, are unsuited.

The names of the different kinds of vine fruit in Hungary are so untranslatable in the West of Europe, and so far off, that they can hardly be identified with those of the West without inspection by qualified cultivators. Thus the Furmint is used in making the Tokay-Ausbruch in the Hegyallya; the Fejér-Szőllő of the same district; the Szemendrian or white Servian grape; the Sár-Fejér or honey grape, believed by some to be the magdalen; the Balafant, the Rók-Szőllő or silver white; the Zapfner which, some contend, is identical with the Orleans of the Rhine; the Hárs-Levellő or linden-leaved; the purple Kadarka or real Hungarian; the Blue of the Banat, the Csoka, or Sloebblack, and a great variety of others, which it would be useless to name, are grown to produce the celebrated wines of Hungary.

The climate of Hungary is peculiar, and in extremes; so that, in some places, they are obliged to bury the stocks to keep them from the cold. The cellars are badly built in many places, and the casks too small, and new and unseasoned wood is continually adopted, spoiling the flavor of the wine. Marble store-vats are used in many places; one at Ofen will contain thirty-nine thousand gallons. That wines ripen best in a large volume, is proved in this district by these vats, or rather cisterns. The wines of the plains are inferior to those of the hills from the same description of fruit.

In Germany, the Riessberg, a small white grape; the Kleinberger, a very productive species; and the Orleans grape—make the more celebrated wines. The Orleans is the favorite at Rudesheim; but all the other wine-makers, except at that place, throughout the Rhinegau prefer the Riessberg. The grapes for the Joannisberger of the first class are carefully selected, and only a small quantity is ever made; about sixteen aums of thirty gallons each. The black pineau of Burgundy, and the teinturier are grown on the Rhine, as well as the chasselas. The traminer, white clüvener, franken, gutadel, frühroth, black clüvener, and muscatelles, are cultivated to a considerable extent in Germany, and on the Moselle, where only the kinds adapted for a Northern class of wines ripen well. This may suffice to afford a faint idea of the great extent to which that portion of wine-making connected with agriculture must be carried, to embrace the entire subject over an extensive and ever varied field.

The grapes depending for perfect maturity upon their Northern or Southern latitude, the vintage takes place accordingly in September or October. Upon the excellence of the must rests the purity of the wine, and that depends much upon the season, the character and soil being the same. The utmost development of saccharine matter is watched until the fruit is ready to burst with ripeness, if all goes on well. The sun having dried up the dew, the work commences; the gathering being expedited most in warm weather, because the fermentation is then most active; and it is desirable to ferment at once the largest possible quantity of must.

The riper clusters are separated from the branches when the skin is thin, transparent, and not apt to break between the teeth; when the color is become deep, that is, when, if the grape be of a white sort, it becomes grey, or if red, from a violet hue appears black; when the stem is woody in fibre, losing its green color, and becoming brown like the main stock, the grape hanging loosely; lastly, when the grain gives way easily to the pressure in gathering, or when crushed, has a vinous odor. The bunches are gathered with great care, for which purpose scissors are commonly used, in order to shake the fruit as little as possible; as the ripe grapes are easily detached, and are bruised with the slightest fall. The baskets—Fig. 616—in which the bunches are placed are small; and the deposition in them takes

Fig. 616.

Osier baskets and mode of carrying the grapes to the press.

place with great care lest the fruit be injured. With large baskets the grapes are crushed; and the must is too often wasted, owing to the superincumbent weight. All the bad or green grapes must be taken off and put aside, as the unripe are apt to impart acid to the sound must. The grapes in different states of maturity are not to be mingled, because they cause an inequality in the fermentation of the must by their acidity, and consequently it is deteriorated. The baskets of osier of a peculiar make are carried to the press strapped on the backs of men, or in carriages. The backs of men, or even of animals, are preferred to carriages, because the motion is less. The stems of the clusters are cut short off. Some farmers take the grapes off the clusters, an operation in France denominated *egrappage*, but the practice is by no means uniform, nor is it universal.

The next part of the process is treading the grapes, or breaking them with machines, before they are set to ferment. This operation facilitates the fermentation. Square troughs are used, having holes in the bottom to admit of the must flowing out. The grapes are then trodden by men with sabots or wooden shoes, at the best, though an ancient, a clumsy, and not very agreeable operation. The must which escapes is thrown into the fermenting vat either with or without the murk, as may be required; and the same operation is repeated until the whole is trodden. The disengage-

ment of the coloring matter from the skins is mainly effected by this process, and no substitute would answer which did not obtain that object. The subsequent fermentation and the heat it produced would not alone obtain and fix the color; the skins must be broken. Several inventions have been exhibited and others carried into practice to meet an end so desirable. Of these machines at a reasonable cost, one is the invention of M. ACHER of Chartres, and has the recommendation of being among the cheapest. This machine is shown in Fig. 617. It does its work well, having the recommendation of the more experienced of the wine-

Fig. 617.

makers that it was capable of giving the must the utmost effect of which it was susceptible, before submitting the grapes to pressure. All were found to be equally and uniformly crushed—none escaping the action of the cylinder. By its use the fermentation proceeds in a more uniform manner, and the action of the press becomes more effectual. A, a hopper in which the grapes are placed; B, a cylinder, one metre in circumference, and sixty-five centimetres in length; it is armed with small nails; the heads large and flat, placed in curved or oblique lines on the cylinders, distant from each other five millimetres. This cylinder is placed beneath the hopper, to crush effectually all the grapes which descend to it. The cylinder is turned by a handle, D; E is a species of wooden flap armed at the lower edge with a series of teeth, perpendicular to the axis of the cylinder, disposed in such a manner as to play between the nail heads on the cylinder, and to crush all the fruit which approaches it; F, the vat which receives the must when crushed.

There is another French invention for the same purpose by a mechanic of Toulouse. It consists of two

horizontal cylinders, which act in the same mode as those of a laminating engine, not only by pressure, but by friction. It moves by means of two toothed wheels attached to one end of each cylinder. In order to communicate to one cylinder a movement more accelerated than that of its fellow, the diameter of each wheel as with its cylinder, is different. A handle is fixed to the end of the smaller cylinder. The larger is ten inches in diameter; the smaller six. These two cylinders are placed at the bottom of a hopper, in which the grapes are deposited. The whole is constructed over a cask or vat, five feet nine inches in diameter, or in length, if of a different form from that of a cask, and this receives the must. It is effective, and dispenses, equally as well as the machine of M. ACHER, with the old uncouth mode of treading out the fruit with sabots.

In order to prevent white wine from becoming colored, the red grapes are not trodden, because it would bruise the skins and discharge the coloring matter; but they are submitted to the press, as they arrive from the vine, and then taken to the vat, husks and all in some places; in others, the muck is reserved after the first pressure. The mode adopted in the use of the little press, which is directed rather to make a little choice than a large quantity of a middling class of wine, is as follows:—Planks are laid upon the bottom of the press, which is uneven, so that the must may run into one channel, and thence into a cask placed below the level of the floor of the press. The grapes are carefully piled on the *maye* or planks at the bottom of the press, other planks are laid upon the grapes, then several transverse beams of wood, and upon these the press is screwed down. The pressure at first is but slight, that there may be no waste of the must. The pressure is then increased until the utmost force of the screw is exerted, and the muck becomes as hard as a stone. The press is afterwards relaxed, the edges of the hardened mass cut square with an instrument for that purpose; and the cuttings being heaped upon the top, the screw is again applied, and the wine thus produced is called, *wine of the first cutting*. This pressing and cutting are repeated more than once. Finally, the muck is steeped in water, and again pressed, when a small wine is the produce, given to the laborers, called in France, *piquette*, and in Spain, *agua pié*.

The wine-press, an instrument as old as the days of the Israelitish lawgiver, is made in various modes in the same country. In Spain at this day presses are clumsy troughs, about eight feet square and a dozen inches deep, with a wooden screw in the centre. Into such a trough, in Andalusia, the grapes are carelessly flung, with a sprinkling of powdered gypsum in making white wine, to saturate the malic acid. The must is received in jars from holes in the trough, and carried thence to the butts. A bar or lever, of about five feet long, is used for turning the screw. The wine-press used in France for the hermitage wine, is a trough seven feet square, having an iron screw of vast power in the centre. This is turned by a wheel having projecting spokes for the workmen to pull it round. There is a stage round the press for the workmen to

stand upon. The grapes are built up in the trough as high as the screw will admit. The must flows from spouts in the sides, at the bottom of the trough. Wine of the first cutting is then taken. This press will make at once forty casks of wine, of fifty gallons each. The muck is generally distilled. In Burgundy, the trough or place for the grapes is twelve feet square, having a lever worked by a wooden screw. There is the *Bascule*, a large press requiring a dozen men to work it. The *Pressoir à étiquet*, moved by levers, or a horizontal wheel worked by four men; and the *Pressoir à coffre*, single and double. One in a vineyard in the Saone and Loire acts by percussion. This press is novel, and is the ingenious invention of M. RÉVEILLON. The press before spoken of as used for making a small quantity of choice wine, in use in France, almost universally, though now somewhat improved, is here represented. In making white wine with red grapes, the want of care in the carriage of the fruit to the press, and the previous pressing, will sometimes cause the wine to assume a tinge of red, which, though slight, is very perceptible, and hence the epithet of *Partridge-eye* has been applied to it. Of course the quality of the wine is in no way altered by this circumstance. There is but one species of grape, the tintilla, which has a colored pulp. The grapes for the red wines thrown into the vat after being

trodden, bruised, and evolving these colors before pressing, it becomes fixed by the heat of the fermentation. In some wines there is apt to be an astringency from the tannin in the stalks, attributable to the desire to preserve the tint; the stalks being acted upon by the heat of the wines, as well as the color in the skins.

Fig. 618.

Fig. 619.

which the rope F runs; E, the cask to receive the must; G, the capstan that turns the wheel and its screw.

The great press, which will make from twenty to thirty barrels of wine in four or five hours, was, in the last century, constructed in the following mode—Fig. 619—and is the most common of the older kind. A A, the base and supporters; C C, the cheeks; D D, great

beams of timber, sometimes four or six in number; E, the screw; F, the nut; G, the wheel turned by five or six men, holding the upright shaft; H, the cage, a square of timber lined with masonry, ten feet long and four and a half square on each side; I, the *maye* or platform on which the grapes are placed, as in the small press, with blocks and planks over them; L, a

grooved channel by which the wine runs into the vat *K*. The cage will rise or sink into the pit; it is here shown ascending, and is in weight a couple of tons. Suspended at the end of the lever by means of its conjunction with the screw, it possesses immense power, increased according to the length of the lever, and thus it rapidly effects its object.

In some parts of the East the grapes are not pressed at all, but are beaten with wooden mallets on an inclined plane of marble, with a gutter at the bottom, which conveys the must into the cask or other receptacle.

On the sublimation of wines by the alembic, now the *still*, to which in recent times the term of distillation is applied, alcohol is separated. The name of this substance is derived from a *el*, more commonly *al*, the mark of the dative case in the Arabic language, joined to the word *coholmo*—in Spanish shortened to *colmo*—to rise to the top of anything; the invention having been brought into Spain by the Arabs.

Hence, too, the word *alembic*—*alambique*. The meaning of the original name was retained in the verb to *sublimate*, *sublime*, or *raise up*, to the head of the chemical vessel or retort. Whether this substance was first sublimated or distilled from the must of the grape, or being of eastern origin, from the fruit of the date, or what other fruit, is uncertain; but in wine it is an important natural constituent. Distilled from the grape, it exhibits a superiority over that from every other substance, existing as it does in a variety of vegetal productions. The mode in which alcohol is formed or evolved by the natural process in the fermentation of the must of the grape, it is necessary to explain; its disengagement from other substances by the still having been already detailed under ALCOHOL.

The preparations for fermenting the must by which alcohol is formed, and the process of wine-making completed, are made with great care on the eve of the vintage. In France where the art is most perfect from superior science, the vats are in some places rubbed with over-ripe Portugal quinces; over those of stone elsewhere, a thin coating of whitewash is passed, to saturate the malic acid in the must. Instead of lime, the wooden vats are by some washed with warm water, and afterwards a little brandy is passed over the staves, while others rub them with decoctions of aromatic plants, salt water, or boiling must. These methods are all beneficial, except the use of the lime, which, without great care and judgment, is apt to detach itself and communicate a bad taste to the must, which is deposited in the vat at once from the receptacles at the press, with or without the murk according to the views of the maker.

The whole of the must being in the vat, the fermentation is the next and most important part of the process. It is divided into two stages; the first rapid, sensible, and tumultuous; the second slow, and of considerable duration. The second is often denominated insensible, though sometimes the escape of the carbonic gas is perceptible to the ear in close-covered vessels. The first demands the access of air to proceed promptly through its regular course, which, although rapid, has always a slight progression to the end

of the operation, which is at once discoverable by its being no longer turbid, and by the subsidence or depression of the head or *chapeau*—as the French denominate the scum, stems, and other substances, which float and form a crust upon the surface of the must, or rather of the wine, into which it has now become changed by the fermentative process—and the conversion of the sugar or glucose into alcohol. The reader will find the particulars of glucose described under STARCH and SUGAR, page 000.

One equivalent of anhydrous grape sugar is resolvable into four of carbonic acid and two of alcohol, whence this deduction:—

Sugar of starch and sugar of milk may be converted into sugar of grapes. In the sugar of the cane, and in that of grapes, oxygen and hydrogen are found in the same proportions as water. Grape-sugar, found also in honey and in most fruits, is the slowest of all sugars to undergo fermentation, during which the sugar is resolved as above into alcohol and carbonic acid by the presence, in only a slight degree, of a substance tending to set it in action. This substance results from the nitrogenous constituents of the grape-juice, and is named *diastase*. In making all natural wines, this substance found in the must comes into action spontaneously. Yeast is the product of decomposed gluten. This yeast added to a solution of pure sugar disappears; but when mixed with juices which contain gluten as well as sugar, it is reproduced by the decomposition of the sugar. Gluten is present in the wine-must undecomposed; decomposed in the state of yeast, it would ruin the flavor of the wine, and should never be used to ferment either grape or domestic wines.

The immediate presence of the fermenting agent at once causes chemical decomposition. Oxygen and hydrogen exist in grape-sugar in the same proportion as they are found in water. Carbonic gas is given out; and in consequence alcohol is formed from the sugar, while water is decomposed during the putrefaction of the gluten. A temperature of 65° is most congenial to vinous fermentation, during which the heat increases. At 60° the fermentation is perceptible, but exceedingly languid. There are instances where it has been known to rise as high as 97° or 98°. Thus the fermentation in warm weather is found to be considerably accelerated. When the weather is cold, boiling must has sometimes been thrown into the vat, and red hot-iron bars have been plunged into the must with the same object.

Fermentation in a very small active mass will communicate the principle to a large quantity at rest. The magnitude of the volume submitted to the operation shows, too, that large quantities proceed more satisfactorily than small, though, in the latter case, the alcoholic strength and aroma are better preserved. After the lowering or fall of the crust or head, the sign of the first fermentation being over, the must is covered up from the air; no more opening being left than is sufficient to suffer the carbonic gas to make its escape.

But there are other substances formed in wine besides those already mentioned—some of which amount to little more than perceptible traces, and these are not found in all wines. Their quantity and even presence will depend upon the nature of the soil in which the vine was grown which produced them, and the cold or heat of the season; for in cold summers the fruit is acid. Starch, gum, albumen, gluten, extractive or coloring matter, bitartrate of potassa, malic, tannic, gallic, and a little citric acid, traces of tartrate of lime, of alumina, and potassa, sulphate of potassa, chlorides of sodium and of potassium, and in some, perhaps traceable in all wines, there are racemates and paratartrates. Racemic or paratartronic acid was discovered by M. KESTNER, and mistaken by him for oxalic acid. It is a modification of tartaric acid, and distinct in its nature. It was first thought to be peculiar to the grapes of the Vosges, and was called *acide de Vosges*. This acid is obtained from a solution, containing as well tartaric acid. The crystals are an oblique prism, with a rhomboid base; those of tartaric acid have a rectangular base. Its formula, as given by GREGORY, is $2\text{HO}, \text{C}_8\text{H}_6\text{O}_{12}$.

There is also an odorous principle called oil of wine, which is sweet, quite neutral, and is formed during fermentation, and obtainable from alcohol by pouring two and a half parts of sulphuric acid on one part of anhydrous alcohol. It boils at 536° , and has a specific weight of 1.133. It has a flavor somewhat resembling peppermint, and imparts a vinous smell to the wine newly formed. The salts procured from this oil are identical with the sulphovinatates procured from sulphuric acid and alcohol. There is also a lighter species of oil of wine, specific gravity = 0.917 to 0.920, resembling olive oil. It is composed of $\text{C}_{16}\text{H}_{16}$, or very nearly the proportions of olefiant gas.

Climate makes an important difference in the component parts of the wine-must, as well in the acid as in the sugar dissolved. Hot climates produce a must rich in sugar; but this difference does not appear to affect the extent of the nitrogenous matter in the must, for it seems to be all expended in some wines before the sugar is converted into alcohol; and a part remaining undecomposed, it produces the thick sweet wines of the South. In colder regions the nitrogenous matter and sugar being alike expended, and the wine as it were balanced in regard to these principles, as in some German wines, dry long-enduring wines are produced. When the gluten is in excess, the wine, not preservable with facility, is soon converted into acetic acid if great care be not taken. It absorbs oxygen, and the oxidation is communicated to the alcohol. This oxidation may be prevented, and the conversion into acetic acid arrested, by the addition of a small quantity of sulphuric acid. Fermentation has been ascribed to the growth of fungi and infusoria; but much more evidence must be given before this can be received as a fact.

To return to practical vinification—the method of treating the produce of the vine in fermentation differs with the climate, season, nature of the fruit, temperature of the vineyard, soil, mode of culture and fancy of the proprietor, who is often guided by local custom. In some places the wine is not suffered to remain in the

vat more than from thirty-six to forty hours. Near Lyons in France, it remains six or eight days, and in general from ten to twelve. In the South-west of France, it remains from twenty-five to forty; and at Narbonne, it is carried up to seventy days. When the farmer is asked how, the fermentation being over and the wine at the temperature of the atmosphere, he suffers it to remain still in contact with the stalks and stems to clear itself in the vat; he replies, It is the custom, and, if warned again of acidity through the breakage of the scum or crust, he answers he only acts according to usage—it should be *ignorance*. It is true the crust is almost always compact; but it is a hazard unless the saccharine principle be abundant, and the albuminous matter all taken up.

Vinous fermentation in general takes place under the free admission of air. An attempt was made by a Madame GERVAIS of Montpellier at the close of the last century, to introduce fermentation in close vessels. The idea was not new. M. DE LA PLOMBANIE, M. PORTA, a Neapolitan, and the German chemist, BECKER, at the commencement of the seventeenth century, had recommended the same process. But the admission of the atmospheric air is indispensable to the operation. A considerable noise was made about the invention, which, it was supposed, would preserve the aroma, and prevent the escape of alcohol. M. DELAVEAU instituted some experiments with great care under a fermentation for nineteen days, when it was found that the return from the vat had the most agreeable flavor; that the wine distilled afforded a spirit only equal to that fermented the usual way; the latter if anything yielding the largest quantity of alcohol. The vat with the invention gave sixteen and a half alcohol at a temperature of 80°F ; the vat with a simple cover, generally used in the South, sixteen and three-eighths; and that not covered at all, sixteen and an eighth. It was thought that the color of the red wines was somewhat deepened by the invention; but neither the aroma nor the vinosity was increased, nor was the invention considered of moment, so as to come into general adoption. Long experience had proved the efficacy of the old mode, and chemistry could find no ground to impugn it in a scientific sense. The strength of the wine, besides that which may be denominated alcohol, or rather its endurance, is in some degree due to the stems and the tannin it contains; but though used in port and some similar second-class red wines, they are excluded from the delicate red wines of France, though adopted in some of the white, while they are also excluded from the Rhine wines. In Spain the wine, having in Andalusia a great enduring power, is left to ferment in the butts, into which it is taken in the *mosto* or must state. The bungs are left open, and the wine and froth thrown up in the fermentation are poured back into the barrel to feed the wine, as they phrase it. This causes a renewal of the fermentation at every atmospherical change, and even on any accidental motion of the cask. In the month of March after the vintage, for the first time, the wine is racked. The advantage of large vats has made no way with the Spaniards. It might be best, *quien sabe*, but he keeps to the old track. The delicate and choice French

wines would be ruined by such a mode of conducting the fermentative process.

On the Rhine the fermentation, after the must is ready made from picked fruit, the stalks put aside, and the different pressings set apart, takes place in casks, to preserve the aroma. The wine is then repeatedly racked, and placed in tuns holding about eight hogsheads and a half, where it remains for many years to acquire perfection. Some of the older tuns, in which the wine no doubt mellow best, are those locally denominated *fuders*, and will contain three hundred and fifty tuns. The celebrated tun of HEIDELBERG has long been renowned. It is thirty-one feet long by twenty-one high, and holds one hundred and fifty fuders, or six hundred hogsheads. It was built at Heidelberg in 1663, as a successor to one which held only a hundred and thirty-two. There was once a larger tun at Dresden, shown in Fig. 620, which held three thousand seven hundred and nine hogsheads.

Fig. 620.

It will be interesting to the reader to know the strength of the must at different periods. The specific gravity of the Pedro Ximenes must at San Lucar, after two days' exposure to the sun in September, was 1.092. At Paxarete in October, its must, after four days' exposure, was 1.121. The must of the Mantuo-Castillan grape at San Lucar in September was 1.069. The black mollat grape at San Lucar gave a must in the middle of September of 1.064; and at Paxarete, the last day of the same month, 1.089. At Chipiona, in the middle of September, the muscatel called gordo-blanco, a large white variety, after three days' exposure to the sun, gave 1.089; at the end of the month 1.096; and in October a specific gravity of 1.114. At San Lucar, in the middle of September, the white Temprana grape gave about 1.075; but, on three days' exposure to the sun, the specific gravity was 1.114. This last grape at San Lucar is cultivated to the extent of nineteen-twentieths of the vine lands. In the Paxarete, Ximenes, Muscat, and Tintilla wines, it enters largely.

In Hungary are made the celebrated rich liqueur wines *Essences*, *Ausbruchs*, and *Maslas*, *vins cuits*, and wines suppressed in fermentation mingled with

other substances, and so long noted for their excellence; the grapes are carried in sacks, for the making, as those of Szamorodny, for example. They are treated in fermentation in the ordinary manner. The fruit or the essence, already obtained without pressure, and over-ripe, is carefully picked upon a large table, called a sorting-table, and placed in a cool vessel covered over. It is then put into a large vat, where men with cleanly washed feet, under a superintendent, tread them into a paste. This grape paste is then placed in a second vat, and covered over. New must of the common wine of the country is then poured upon it, the quantity of which used determines the quality of the wine, or wine *de liqueur*, according to the owner's pleasure. Sometimes two measures, or four, five, or six of the essence are added to ten of the common wine. The proportion of six to ten is rarely exceeded. The wine and paste are then mixed, and left for a couple of days, or for three, if the tempera-

ture be low, stirring the mass frequently. This thick must is then conveyed to the press, a slight pressure producing the richest kind; it is next conveyed into a cask, and thus becomes the celebrated Tokay Ausbruch, or flowing syrup. It is skimmed while fermenting, and strained into casks. It has a fine aroma, but never becomes very bright. It is soft and oily on the palate. There are two species, one containing generally sixty-one parts of essence, and eighty-five of wine; and the other called *maslas*, having sixty-one parts of essence to a hundred and sixty-nine of wine. The best sells for twelve pounds sterling the dozen. The fermenting and purifying proceed together. That of 1811 was celebrated, the fermentation having been perfect. There is besides a great variety of wine in Hungary, but all of a peculiar character.

The greatest care in manipulation, and the most scientific methods in the treatment of wine, have been tried in France, and the result has been the production of the finest wines in the world. The removal of the wine from the vat to the cask is there as carefully regarded as the work of fermentation. The casks are all made ready at the same time as the vats. If the wood of which they are made is new, they will not fail to communicate an astringency and bitterness to the wine. To prevent this, the casks are repeatedly washed with cold water, and then with hot, in which peach leaves and salt are infused. They are repeatedly shaken while the fluid is hot, and then are left so that the wood may absorb them, and they may penetrate into the pores of the timber. The casks are now emptied, and boiling hot must, to the extent of two or three quarts, is introduced. The bungs are put in, the casks shaken, and then left to cool. Some use only hot wine in place of the above substances. If the casks are old, they scrape off the tartar that lines the staves, and wash them with hot water and must, or wine. If they have contracted an ill smell, or show the least mark of decay, they are burned at once, because, in

spite of all that can be done, sooner or later the bad effects will appear. Casks should be sulphured, if the least suspicion attach to them, by the introduction of a match at the bung. Such casks are generally made of oak staves, but some prefer beech. They bear different names in different parts of France, as *barrique* at Bordeaux, *botte* at Lyons, *tun*, and *pipe*, *et cetera*, in other places. When large, they are called *muids*, and very large ones *foudres*. Some have proposed vases of clay varnished, but they are considered porous, and cannot be easily conveyed from place to place.

The wine being fermented, the duration of the fermentation, depending upon the state of the temperature, the amount of sugar and similar things, to be decided upon observation and according to the season, the wine is drawn off into the cask. Some of the finest Burgundies, called wines *de primeur*, only remain in the vat from six to ten hours. The rest in the vat is only important on account of the color. If the skins were sufficiently broken, so that the coloring principle stands in no need of the action caused by the tumultuous fermentation to bring it out, the fermentation with the fruit and its grains being often more mischievous than useful, it is omitted. If the skins are sufficiently bruised and torn, when the fruit is trodden, to give out all the coloring matter, it is not considered wise to suffer the must to enter the vat after pressing.

The drawing off the wine into the cask at the exact moment is a point of great importance. The crust or chapeau having fallen, and active fermentation ceased to the eye, all being perfectly quiet, the examination with a wine glass, the taste, color, and odor, except tested by experience, are often fallacious. Taste and smell are so different in individuals that there is much uncertainty upon the time when it is best to operate. The heat generated in fermentation depends mainly upon the quantity of glucose or grape sugar which has entered into the spirituous state. No fixed rule exists. It is frequently found that the maximum of heat is attained after twenty-one hours of fermentation in one case, and in another after ten, while the wine is not really perfected perhaps for twenty hours longer, so that the thermometer is no reliable guide as to the vinification. Something to determine the fact of the vinification mechanically, was long considered a desideratum by the French producers. There were the differences of climate, soil, and species of fruit to be considered. An attempt was made to ascertain this point by means of a vertical rod, marked with a scale to show the elevation and depression of the fluid. It was placed in the middle of the vat to indicate the depression of the must after its previous repulsion by the fluid, and that the time thus indicated should be that of drawing off the wine from the vat. This was found to be correct in seasons when the sugar was abundant, and then the moment of the retrogradation of the must was the best for emptying the vat. In wet seasons, on the other hand, the indicator did not seem to answer, but the inventor had little doubt of success in establishing a scale to indicate the time sought in different seasons when the temperature varied; but he was unable to carry out his experiments beyond three seasons, having been compelled to become an exile.

In drawing off the vat it is necessary, before commencing, to take away with great care, by the use of a wooden shovel, that part of the head or crust which, having contracted acidity by exposure to the air, if it broke and became mingled with the must beneath would spoil the whole mass. The must drawn off, the murk remaining in the vat is pressed for the wine called that *of the press*, which is equal in quality to that which has been drawn from the vat without pressure. The wines thus made are called that of the first, second, and third vatting, as before stated. The first taken is the most spirituous, and the last the harshest, sharpest, and deepest-colored. The second pressing holds a middle quality. The residue of the murk is used for the manufacture of verdigris, for the food of cattle, for vine-dressing, or for nourishing pigeons, which greedily devour it. These later wines of the press are sometimes mingled with that of the vat, an indefensible practice, because the wine from the vat will often by such a mixture lose its own peculiar delicacy.

The wine being in cask is, in the pure wine countries, directly placed in the cellar. The cellars vary in different countries. In Spain those of the Xeres district are of great size, to the extent of three hundred English feet long by above two hundred broad. Four thousand casks of wine are arranged in similar cellars in tiers, and are called *soleras*. The wines of different seasons are mingled in these, so that one will contain some of each vintage for thirty seasons. The wine is fermented in the butts, the bung-holes being left open without endangering the wine; nor is the cellar temperature much regarded, such is the firmness of the wine. In Valladolid the cellars are deep in the earth, like mines, with huts over them. In France the cellar is an object of peculiar care, the exquisitely delicate wines of the first-class in that country demanding great attention as to safe-keeping in their highest and most perfect state. The best and favorite cellars are held to be such as are situated under uninhabited buildings, as is observable in the places most noted for the culture of the vine, having a Northern exposure, and fifty or sixty feet deep, according to the dryness or the humidity of the soil. A uniform degree of moderate humidity is best. A cellar too damp causes the decay of the barrel staves, or covers them with a mouldiness which communicates a bad taste to the wine. If a cellar be too dry it makes the staves of the casks shrink, and the wine is wasted by leakage. The air should be admitted only by small openings, facing the North, made near the roof or vault, and susceptible of being closed when the weather is too hot or too cold. The vault or roof should be as solid and thick as possible, in order that no external concussions should be communicated to the wine. The soil above the vaulted roof should be united and well beaten down, and that part designed to receive the bottled wine should be covered with sand or fine fresh-water gravel.

The casks should be placed in a position perfectly horizontal, upon wooden beams six or seven inches square, supported by others transverse. Wedges should be forced under the casks on each side to keep them steady, and neither the casks nor their supports should

touch the wall of the cellar. If the casks are not set perfectly level, the wine lees will collect in the back part and prevent the wine flowing clear out of the cask the usual way. If the front be too much raised, the lees will come to it when the cask is elevated behind, in order to draw off the last of the wine, and thus stop the passage. The lees should settle in the belly or hollow of the staves, which will take place when the casks are kept perfectly horizontal with wedges, as shown in Fig. 621. Attached to the cask here given is

Fig. 621.

an air tube, to illustrate the mode adopted in some parts of France to prevent the admission of air over the wine, so apt to cause acidity.

The tube or canal, *abc*, is of the common form, except that the bottom of the tap at *d* is pierced with two apertures, of which the lower serves for the passage of the liquor, and the other corresponds with tube *efgch*, by which air is introduced into the tube to replace the liquid drawn out. The result is that it suffices to turn the tap, *k*, to cause the liquid to run; and to shut it, that all communication with the exterior air shall be cut off. It is evident that when the tap is turned the wine will run out, and that the exterior air will replace that wanting by the tube *efgch*, and that on shutting, *k*, the pressure of the air will cease with the running of the wine. The tube is carried higher than is necessary, that the wine may not enter the tube at *h*, and may have the least possible distance to the surface of the wine, and thus prevent agitation. The tube at *h*, and the tap at *b*, both enter the cask. When the cask is to be all drawn off at once, of course such an application is superfluous, but it is invaluable where small quantities are taken in draft.

No garden stuff, green wood, flowers, fruits, or similar substances must be permitted in any cellar in which wine is kept, because the gas disengaged from them promotes aescency. The wine being deposited in the cellar, the insensible fermentation commences but too sensibly if that in the vat was imperfect. Carbonic acid gas still makes its escape, augmenting the volume of the wine, and forcing itself out at the bung in froth or scum. Hence it is necessary to take care that the casks are not quite filled when they leave the vat. At least two inches' space is left, and the bung driven home to prevent the slightest entrance of the atmospheric air. A gimlet hole is made on the upper side

of the cask, and stopped with a peg or *fausset*, in order to let the carbonic gas escape. Some wine-makers place in the bung-hole a linen cloth, filled or covered with sand or vine leaves pressed down with a tile.

When this fermentation ceases, and the wine has sunk down, the cask must be filled up and hermetically closed with linen round the bung. The operation of filling up by the bung is denominated *ullage*. In some places ullage is performed every day for the first month, every five days for the second, and every eight until the wine is racked. The celebrated Hermitage wine is thus treated. At Bordeaux ullage is performed on the eighth day—filling up exactly every ten days during the first month, and then once a month to the time of racking. In other places, if the cellars are dry, twice in two months; if humid, every three months. Ullage is performed in fine weather with wine fully equal in quality to that in the cask. The cellars are to be visited daily to guard against accidents, such as a leak in a stave from a wormhole, injury from commotion in carriage, mouldiness of the staves if the cellar be too damp, or shrinking of the staves or heads in those which are too dry. The wine from time to time is tasted, to ascertain its state and remedy any perceptible mischief. When ullage is neglected, a white mouldiness, called the *Flower*, is observed on the surface of the wine—a certain forerunner of acetous degeneration. The air is at once forced out, the nozzle of a bellows being introduced for that purpose, and then it is agi-

Fig. 622.

tated. A sulphur match is introduced, and the bung inserted. The cask is struck from below, to raise any concealed air bubbles to the surface, and to carry all the mouldiness possible to the bung-hole, which is filled so as to make the wine run over, and these efforts are continued until no vestige of the *Flower* appears. The wine in the cellar is observed to work much when the vine commences to bud, and when the fruit ripens,

which BUFFON attributes to the changes in the juice of the vine. FABBIONI and other authorities have stated that this phenomenon is only observable when the particles of the wine have not been separated by a sufficient quantity of alcohol—in other words, when the glucose was not equal to the subjugation of the gluten, and the other constituents were not in due proportion. This fermentation is prevented by the use of sulphuric acid, sulphate of lime, mercurial oxides, additional alcohol, camphor, ice, and water at the boiling point. When the wine is still, it is perfected, and only deposits its lees, consisting of portions of the pulp of the fruit, of the coloring matter, and of the tartar, which last is found crystallized on the interior of the staves of the cask.

The next process is that of racking, undertaken to clear the wine of the substances which tend, by mixing anew with the wine, to form a fermentation. It is an operation not generally performed at a stated time. In some places it is done in December, after the vintage, when the wine is required to be moved; if not, it is done annually, generally in the months of February or March. In some countries this operation is performed twice the first year, in spring and at the end of September; in others, at the end of December and middle of May—the first during a sharp frost. Much, however, depends upon the quality of the wine. Generous wines may rest upon the lees three or four months, and be only racked once in two years, but in general they are separated from their lees before the first equinox of the spring succeeding the vintage. There are times when, on the other hand, in lieu of racking, it becomes necessary to recombine the lees with the wine, in order to establish a fermentation which may ameliorate them and promote their maturity. This operation being of importance, it is necessary to describe. The smallest inadvertence will produce, in conducting it, the acetic action, the tendency to which, the moment it is perceived, must be met by racking at once, and moving it to the coldest place possible, and before racking it must be fined. The weather most proper is that which is dry and clear.

The wine is drawn off carefully that it be not disturbed, and when the cask is stouped for the last of the liquor, it must be done with great care and judgment by hands accustomed to the operation. The Beaune wines in France are generally racked by the introduction of an instrument into the cask well calculated to draw off the fluid without disturbance, and these wines are always remarkably fine. At Condrieu on the Rhone, the wine is racked eight days after it is made, and before the end of the month it is fined, then racked anew, sometimes twice or thrice at an interval of fifteen or twenty days, in order to procure the limpidity so desirable. Wines not cleared sufficiently by racking are fined, the substances used for the purpose being isinglass and whites of eggs. The isinglass is cut up and steeped in a little wine, until it becomes viscid and softened. It is then thrown into the cask. The wine is afterwards strongly agitated. The quantity of finings used is about five drachms to every five or six hundred litres or quarts of wine. The whites of eggs, preferred in some places, are well beaten up in a little wine, poured into the cask, and left to rest for ten or fifteen

days, when the wine is racked during the first Northerly wind. From six to ten fresh eggs are used for every twenty-two gallons imperial. Various substances have been applied for the purpose, as gum-arabic, hartshorn, calcined flint, rice, milk, and starch, but none produce the desired effect so promptly as isinglass or the white of the egg. Ordinary wines lose their acidity by fining, and the finer classes increase their brilliancy and clearness.

Wine is sulphured at times, in other words, impregnated with sulphurous gas, by burning sulphur matches over it. These consist of a roll of linen or cotton an inch and a half broad, and six or seven long, dipped in melted sulphur, to which powdered leaves of aromatic plants are sometimes added. Those made at Strasbourg are noted. The match is suspended from the bung-hole by a wire, and being lighted, the bung is closed. The air within dilates and escapes through the smallest opening. The operation contributes greatly to the preservation of the wine, though some say it injures the color of red wines. Those who object to it throw a little brandy into the cask, to which they set fire with a bit of lighted string, and while it is burning close up the bung, leaving only just air enough to keep up combustion. In other cases a wine is made; the fermentation is arrested, and the must placed in a cask until it is a quarter filled, and a number of sulphur matches are burned over it. The cask is then closed and strongly agitated, until no gas escapes on opening the bung. More must is then added, and the agitation repeated, until the cask is full. This must never ferments, has a sweet taste, smells strongly of sulphur, and when a certain quantity of alcohol—of the strength *trois-six*—is added, a wine named *wine of Calabria* is the product, employed principally to give strength and sweetness to wines deficient in those qualities.

MULDER states that wine, stored in wooden casks, loses water, whether mixed with alcohol or not. But if evaporation affects the contents of the cask, the loss must be repaired, otherwise the action of the air would turn the wine acerb, and convert the alcohol into acetic acid. It is chiefly water which is evaporated, and its loss is made up by adding wine. All the constituents of wine, with the exception of water, are hereby increased, and the wine becomes not only stronger, but better flavored. The vinous components being more concentrated, are better able to act chemically upon each other, and this, *per se*, would account for the improvement of the wine. Here one has a general statement of the causes upon which the difference between new wine and that which has been stored in casks mainly depends. But the change is carried still further. The concentration of the wine, or rather the diminution of water, which is continually replaced by wine, causes a constant augmentation of tartaric acid in the wine. Wines which are poor in sugar may easily become too sour, and all wines cannot, therefore, undergo this process. The quantity of tartar in the wine is not increased; for, being insoluble in alcohol, the continual increase of alcohol precipitates it. That which is augmented is tartaric acid, which is soluble in alcohol, and insoluble in cream of tartar.

Madeira, and such like wines, are sent to warm countries to improve. MULDER had Madeira which had been seven times in cask to the East Indies and back, and truly, says he, *such nectar was unknown to the gods of the ancients*. The drier the atmosphere is which surrounds the casks, the greater will be the evaporation. To avoid this, care must be taken to prevent draughts, and to keep the air of the wine stores or cellars moist.

Wines remain in wood different periods, according to their qualities, and while thus resting are in a state of improvement. Some repose only three or four years before bottling. Tender, delicate, light wines gain little in the bottle, while strong spirituous ones preserve well in that state, and to a certain point improve. In bottling fine wines the bottles and corks should be new; the smallest defect in the latter determining their rejection. The French dip the corks and the bottle necks in a composition differently colored, to distinguish the wine, and thus shield the external part of the cork and a little of the neck of the bottle with it from the action of the air. This composition is made for three hundred bottles with two pounds nine ounces of rosin, half that quantity of Burgundy pitch, a fourth of yellow wax, and a small quantity of red mastic melted together, so as to form a liquid mass in which the corked necks of the bottles are dipped. In the cellar the bottles should be placed horizontally, to keep the corks always wet. Fine fresh-water gravel or sand is their best bed, and keeps the wine cool, but sea-sand from the salt in it, is pernicious. Sawdust only answers for coarse wines.

Wines of fine quality can only be mixed with others of a like quality to render them more generous, or to have a larger quantity of one particular flavor. It is a robbery or a great abuse to sell wine mixed in any other way for a genuine growth. Wines of Bordeaux are sometimes strengthened with hermitage or wine of Cahors, and are known as Medoc wines; but they are genuine and of good quality. Wines are liable to alteration and to degenerate. Such are loss of color, bitterness, acidity, tasting of old, of the wood, of musk, mouldiness, and what the French call *graise*, milkiness or cloudiness. To amend the last they use pure tartaric acid, taking care that little of the carbonic gas given out shall escape from the cask. This acid is composed of 2HO , $\text{C}_8\text{H}_4\text{O}_{10}$ and is found in a good many fruits beside the grape. The acid is mingled with sugar and introduced hot into the cask, which is closed and agitated for five or six minutes. Two days after, the wine is fined in the ordinary way. The carbonic gas is the agent of the cure. Wine is sometimes passed over fresh lees as a remedy for the same disease; and then racking is had recourse to afterwards. Acidity generally attacks wine which wants body. This never amends itself, but proceeds to the acetic state if left alone. Taken at the earliest moment, it is transferred into a cask impregnated with sulphur by the means before described; and different modes are employed for the cure of the mischief. Some dissolve honey, others liquorice, in the wine. Acetate of magnesia, bone gelatin, and similar substances are used; but the best mode of cure is to pass the wine over the relics in

the vat, after the vintage product for the year has been drawn off. Even then it should be drank early, for it cannot be trusted over another season. Oftentimes the acetous fermentation has already commenced, and there is no resource but to leave it to the vinegar-manufacturer. The bitterness in wine will sometimes become cured by itself when in bottle. It takes place in old wine. If not cured by passing the wine over fresh lees or mingling new with that attacked, it should be reserved for the still. Loss of color generally happens to the deepest-tinctured wines approaching age, arising from a species of fermentation for which recourse is had to purified tartar reduced to a fine powder and mingled. If unsuccessful, it must be mixed with a younger growth. The taste of old and musk—the latter thought to be caused by insects—the depositions of different wines, and the taste of the wood, add to the multiform cares of the wine-grower and admit of a variety of applications for cures not always successful. There is a wide road here for chemical investigation and experiment yet untrodden, as there is also to determine exactly those constituents which give to certain wines their delicate aroma and flavor. The odor which is peculiar to all wines must, to a certain extent, be ascribed to enanthic ether.—*Vide* ALCOHOL, vol. i., page 105.—The volatile substance existing in wine, which imparts to it, conjointly with enanthic ether, its vinous fragrantcy, is alcohol. Other beautiful volatile compounds have been detected in wine, but there is much yet to be discovered. To what substance does a fine Sauterne owe its most peculiar but magnificent bouquet? Acetic ether appears in most, perhaps in all, aromatic wines, and is developed in them by time. The adulterators of wine are well acquainted with this fact, and know how to make use of it. Acetic ether is largely sold for this purpose, and added in proportionably small quantities to wines which are not aromatic, to improve their fragrantcy. Two or three drops are ample for a bottle of wine. The reader is here referred to the article ETHER, vol. i., page 832, for full particulars with regard to the properties, *et cetera*, of the delicate ether existing in wine and spirits.

Besides the wines denominated sweet and dry, prepared from the fruit in the mode, and their difference arising from causes already stated, there are prepared wines in which the must is concentrated by evaporating a portion of the aqueous part, a very ancient custom wherever wine of the usual kind is made, called in France *vins cuits*, in Italy *vino cotto*, and in Spain, from the Arabic, *arropé*. The wine is boiled down to a third part, being skimmed of its froth, and sometimes, while boiling, aromatic substances are infused, or else it is used in its unperfumed state for strengthening other wines.

Dry and sweet wines, or wines of *liqueur*, are distinguished principally by the saccharine principle, in sweet wine, not being all converted into alcohol, the glucose surpassing the gluten in proportion, and the change being in consequence only partially effected. Such are the wines of Malaga, Rivesaltes, and Frontignan, and the wines from the rich muscatel grape more especially. Straw wines are also sweet wines, made of grapes for some months suspended upon straw bands

and afterwards pressed and fermented. The produce is about a sixth only of that obtained at the vintage. It has a strong rich flavor of the dried raisin. There is also a wine called *de Grenier* in France, made in nearly the same manner, and a sweet white styled *de Garde*.

Another wine of a very distinct character and of two kinds, one drier than the other, is procured by suppressing the fermentation, in other words, retaining the carbonic gas to a considerable extent. This species comprehends the wines of Champagne and their unworthy imitations, called sparkling Burgundies, Moselles, and others, all managed in the same mode. There is a genuine wine at Arbois of the same kind, or *mousseaux*, as the French term it, made in a mode somewhat different. The crust or chapeau is allowed to rise and settle over the must, as in the common mode of fermentation, so far as that the fermentation is not visible and no further, in order that the wine may be racked off in a clear state, being watched day and night for the period when bubbles of carbonic gas begin to appear on the surface. It is then racked into a vat and remains until a second crust or scum forms, and this is repeated until the wine is perfectly limpid. It is now placed in casks carefully kept filled. The bungs are daily examined in case of starting, that the cask may be filled up immediately. The air is excluded when the fermentation ceases, racked again in January or the following month, and in March fined and bottled. The corks being wired, the wine is deposited in a cellar of the requisite temperature.

To return to the more celebrated wines of Champagne, distinguished as still, creaming, and sparkling wines, or *mousseaux*, *crémans*, and *non-mousseaux*, of which the two last are most in esteem. The best froth very slightly, as Sillery; and the finest, called *vin du roi*, not at all. These wines come from the banks of the Marne and constitute a unique class. They are made for the most part of the blackest grapes, gathered with care, and only the sound fruit used. The grapes are carried to the press in baskets, covered up from the sun, and placed on the press with as little motion as possible. The must is poured into a vat for a term of from six to fifteen hours, that the dregs may be deposited. As soon as ever fermentation appears, the wine is transferred to the cask. The product of the first pressing is set aside as the choicest. The second pressing, or the wine of the *first cutting*, lightly colored and spirituous, partly composes the effervescing wines. The wine of the third pressing is kept for giving strength to the ordinary red wine of the country. This wine is put into bottles in March or April. At Rheims, on the other hand, they bottle the Sillery in January, although at the risk of its imbibing the effervescing quality. It having been thought advantageous to secure champagne of a uniform quality, which it was difficult to do from its being put into small casks; tuns holding twelve thousand litres were a few years ago introduced at Rheims by a German house, and the advantage of their use became evident.

The next step is to procure bottles of great strength, free of air bubbles, of the exact size, and without a flaw. The number required to bottle the effervescing wines in the department of the Marne is enormous; eight hundred

and sixty-six thousand gallons having been bottled in one season in the arrondissement of Epernay alone. In March or April the bottling commences. If done earlier, the breakage would be greater, fifteen per cent. being the ordinary loss. In the fermentation the carbonic gas not being allowed to form sufficiently or fully develop itself in the cask, it is quickly reproduced in the bottle; the saccharine principle renews its progress towards alcohol; and if the latter be sufficient to prevent the decay of the wine, the quality is good. This wine does not effervesce in uniform times. Some kinds will do so in a fortnight; others will be months before the signs appear. One wine will require a change of temperature for the purpose, and must be brought up nearer to the surface of the ground, if the cellar be deep. Another kind will not exhibit itself until the month of August, and a third kind only at the time the owner's patience is almost exhausted, when it will appear unexpectedly. If a wine shows no sign the first year, it is mingled the next year with new wine known to possess the effervescing principle. Nothing is certain; the cellars, their soil and depth, the air-holes, the difference of the place of growth—all seem to have an inexplicable effect upon the operation.

The bottles, carefully cleaned by rinsing and shotting, are placed in the working shop or *atelier*. The barrel-heads are bored, and a small brass pipe with a gauze-strainer, is inserted. The bottles are filled so as to allow about two inches clear space between the cork and the wine. This space diminishes, while the carbonic gas is generating; and the fractured bottles show that the expansion of the fluid has primarily quite filled the void. A workman who fills the bottles passes them on the right hand side to the principal operator, who is seated upon a stool, with a little table before him covered with sheet-lead, and about as high as his knees. He inspects the allotted space between the cork and the wine, regulates it exactly, selects a cork, moistens it, introduces it into the bottle, and strikes it so hard two or three times with a wooden mallet, that an observer wonders it is not broken by the violence of the blows; and yet fracture this way is rare from the attention paid to the management of the bottle at the same moment. This workman then passes the corked bottle to his right, where a third workman, seated precisely in the same manner, crosses the cork with pack-thread, and ties it strongly. He then passes it to a fourth workman who wires the bottle, cuts the wire, and hands it to a youth who places the bottles upright in the form of a parallelogram, so that they can be counted in a moment. The daily labor is calculated at a drawing of from sixteen hundred to seventeen hundred bottles. The best cellars of Epernay are those of M. MOET, and the bottles run in a pile from end to end, six feet high, and are carried down in osier baskets, having in each twenty-five cases for the bottles. Two men carry them by leather belts drawn through the handles of the basket. Slopes are prepared beneath in cement to carry away the wine from the broken bottles in the piles, with reservoirs to collect it. The bottles are placed head to tail on laths, the corks one way the reverse of the other.

The piles are very solid; and any one of the bottles, with the neck to the rear of the pile, can be easily with-

drawn in order to examine its state, and see if the carbonic gas is developed. If not, all must be got into the proper state, cost what it may. When a bottle is drawn from a pile, and kept in a horizontal position, a deposition is generally observable called the *griffe*, or claw, from its branching appearance. Before a bottle breaks, the vacancy below the cork disappears by the expansion of the carbonic acid, which generally occurs in July or August, when commonly from four to ten per cent. of breakage is experienced; too often the mischief reaches from thirty to forty. Sometimes, of the same wine in the same part of the cellar, one pile will remain with the gas undeveloped, while the other shows no sign of effervescence. A current of air will sometimes make the wine effervesce furiously. Thus great expenses are incurred, not only by breakage, but in attempts to excite the carbonic development. The loss by the breakage is often not equal to that of correcting the inertness of the wine, independently of the trouble. If not exceeding ten per cent. in breakage, the maker is satisfied. If it is deemed necessary to take down the pile, the bottles are set upon their bottoms for a longer or shorter time, and this causes a difference in the quality of the wine. At one time it is removed into a deeper cellar; or, lastly, the bottles are uncorked to disengage the gas, and clear the space under the cork. When the carbonic gas is furious in its development, the wine is wasted in large quantities. The wine of the broken bottles becomes scattered among the sound, or fragments remain which contain wine, and become acid and even putrid. The gutters become infected, and in the air of the cellar new principles of fermentation ensue. In August workmen have been obliged, owing to the fragments of glass projected from the piles, to put on wire masks, and entering the cellar to throw cold water over the wine. The breakage ceases in the month of September. In October the piles are *lifted*; the bottles being taken down one by one, putting aside those broken, and placing on their bottoms those in which, on examining the necks, the corks and sealing seem to have moved. Some bottles are found to have lost a portion of their contents, and the loss must be repaired. The deposition, too, must be removed. For this purpose the bottles are placed in an inclined position of about 25°, and are shaken two or three times a day, to detach the sediment, for ten or fifteen days successively. Planks with holes in them receive three or four thousand bottles together, keeping them in the right slope. The workmen then, with considerable dexterity, get all the deposition into the neck of the bottle, near the cork, the wine being perfectly clear. Every bottle is then taken by the bottom, kept carefully reversed, and the wire and twine being broken—the bottle resting on the workman's knees—the cork is dextrously withdrawn, so as to permit the gas to explode, and carry the deposition with it. An index is then introduced into the neck to measure how high the wine should ascend, and the deficiency is made good with wine that has before undergone the operation. The bottle is then a second time corked and wired. If the wine remain long in the cellar afterwards, before it is sold, it is submitted to a second clearance or *degorgement* of a similar kind about a fortnight before it is sent away; the

process to the last being laborious and expensive. These wines do not admit of being mingled with any but those of their own growth, and those genuine are rarely mingled at all. Grey champagne is made by treading the wine slightly before pressing, and rose-colored by a longer treading; but the latter is generally wine of inferior quality. In good cellars these wines will retain their excellence for twenty, and even as far as thirty years, in the last case imbibing only a slight degree of bitterness. The temperature of the cellars in which the wine is kept, is best at about 53° almost unvaryingly. The receptacles at Epernay are excavations in the calcareous rock, thirty-five feet below the surface of the ground. The creaming and still wines keep the best; those very frothy are most liable to change, and are really the least worthy of the class.

The finest red wines in the world are those of Burgundy, in the district called the Côte d'Or. They are produced principally from the grape called the Pineau. From twenty to thirty hours in the vat are sufficient to convert the glucose into alcohol, and then in two or three years they are fit for drinking. If moved in the cask in the least as they deposit, they are apt to spoil. On this account the finer kinds are only removed in bottle, and should be kept with great care. When old they take an amber color. In England the first classes of these wines and their proper management are unknown; the second classes alone being imported as the first, the coarse taste of the English palate in wine preventing the discovery of the difference. The finer wines are all produced in the districts of Nuits and Vosne; of these the Romanée-conti and the Chambertin are among the more celebrated. The white wines of the same district are not so well known or esteemed as the red. In the Mont Rachet wine, a celebrated growth, made near Beaune, occurs one of those extraordinary phenomena in wine which no scientific investigation has succeeded in explaining. Three kinds of wine are made of fruit grown on the same land, so contiguous as only to be separated by a footpath, having the same exposure, the soil appearing the same, as well as the species of vine; yet the last brings only one-third the price of the first. The whole ground is about thirty-seven hectares, of which the most prized is but seven, the next quality eighteen, and the third twelve. The wine of the first fruit sells at twelve hundred francs, the second six hundred, and the third four hundred.

The climate of Italy so congenial to the vine, produces no wines of export much valued, owing to the ill management of the vintage. No attention is paid to sorting the grapes; ripe and unripe are thrown into the vat together. Nicety and even cleanliness are neglected. The grapes are trodden and thrown into a vat, where the must remains fourteen days in a state of continued fermentation until the wine is spoiled. Sometimes the must is left exposed to the air for a month together, and the wine, ill-managed, has no reputation. In Tuscany more attention is paid to the process than in other parts of the country, and very palatable wine is made, but with little improvement in the process. The Montepulciano is a sweet wine long

noted there. This wine is racked repeatedly for two months after it is made, but the fermentation is often continued until the wine has begun to contract acidity before it is removed into the cask. In Naples they make a sweet wine called *lacryma Christi*, but the process is as careless as in other parts of Italy—in fact there are four or five wines of that name, some pretty good, others execrable. In Sicily the Mazzara wines, and the sweet wines of Syracuse, are made with little care; but English capital and some pains having been bestowed on the Marsala and Etna wines, they are exported to England, according to custom, brandied to excess to save care in their management, or, as the phrase is, to *fortify* them. The Marsala wine, well treated, is sound and good, and made in the fine climate of Sicily with French science, might still be greatly improved.

The Greek islands produce wine of various kinds, but mostly muscadines. In Cyprus the grapes are not suffered to lie too numerously on the stock. They are of a rich purple, with a thin skin. The vintage begins at the end of August. For the celebrated wine of the Commandery, the fruit is placed on covered floors called *punsi*, and spread out with care in a bed of eighteen inches thick, where the grapes remain until the seeds or grains are ready to drop from them. They are then carefully lifted with wooden shovels and carried to rooms paved with marble, or covered with a cement equally compact. These floors are made of a gentle slope. The grapes are bruised with a wooden mallet, and pressed in little presses denominated *patitisi*; the must, which is very thick, flowing into a vessel on the lower side of the floor. This vessel is emptied, when full, into small vases, and in these conveyed into baked earthen vessels with acute bases, like the ancient amphoræ. In these the wine is left forty days to ferment, in some places with the vat covered while in that state. This wine, if taken while in a state of fermentation, causes severe colic pains, to prevent which it is filtered through bags of vine ashes, but when thus treated it never attains the perfection desired. When the fermentation has ceased, the wine is shut up from the air with covers of baked earth, and has already put on a lighter color than before. These vessels are either coated internally with pitch, or varnished the instant they leave the potter's hand. If varnished, the composition consists of a boiling liquid in which turpentine and pitch are mingled with vine ashes, goat's hair, and fine sand; this effectually closes the pores, and never falls off. The art of making these vessels belongs to the remotest antiquity. They hold from twenty to thirty barrels each and in them the lees are deposited, which are called *mana*. When removed, leathern bags are adopted, pitched on the inside, and detrimental to the wine, which does not for many years lose the disagreeable flavor. The cellars, in so hot a climate as Cyprus, are all above the ground; little light is admitted, and the aspect disregarded. This famous wine was named from the Commander of the Knights Templars, to whom the district once belonged. The Commandery wine resembles the Italian wine of Chianti in color. From a red it changes to a yellowish hue the first year, fines itself as it grows old, and in nine or ten years takes nearly the same appearance as the sweet wines

of the South of Europe. The dregs are thick, and supposed to aid the fining. When brought from the country to the town and put into casks, it is always in such as have lees remaining, in which it is left for a year. Whether ullage is attended to or not, it makes no difference in regard to the excellence of the wine, for sometimes a cask is left not three-fourths filled. It is sold at the vineyard by the load of sixteen jars, each containing five Florence bottles. The wine is warranted good by the seller until the August after the vintage. It is generally exported in casks of three hundred and fifty bottles each. Only about ten thousand jars are now produced. When poured into a glass, if good in quality, the particles adhere like oil to the sides. Cold injures it; in a Northern climate it must be placed before a fire. The lees are always treasured up, and are often in color a mixture of black, red, and yellow, though generally like Spanish snuff. Those wines and the muscadines of Cyprus are different. The wines of the Greek islands are mingled with rosin to impart durability, and are very disagreeable to the taste in consequence. The wine of the Crimea, at least that called *kokour*, is fermented coarser than in Cyprus. The vats in many places are only pits dug in the ground, plastered with a composition. The Shiraz wine of Persia is made of trodden grapes, fermented in jars of glazed pottery agitated briskly; it is then bottled for sale.

The wine of Portugal, forced upon the people of England in 1703, by rendering the duty on that wine a third less than on the produce of other countries, drove out many fine wines, of which there was a great variety before, and forced an inferior article upon the public, under the absurd idea that Portugal would take English woollens in return, as if all trades were not an exchange of goods. The effect was to drive all variety in wine out of the country, and make Englishmen take an inferior article. At first the wine came in its natural state, but was afterwards sophisticated and brandied. Efforts were too soon made to control the market by limiting the supply, and rendering the wine nearly of a uniform quality. After the Portugal wine monopoly of 1756 was established, brandy was added, and increased until, in recent times, no less than from twenty to twenty-four gallons per pipe are flung into the wine during and after fermentation. In its natural state this wine is not permitted to come to England. The growth is stunted because the export is limited by a privileged company, which creates an artificial scarcity. The wine is adulterated with a mixture called *geropiga*, two-thirds must, and one-third spirits 20° above proof, with elderberry juice and sweetening matter, and is sanctioned by the English Government, though a gross adulteration, being admitted here as a spirit to carry out a fraud. This medley is used only in preparing wines for England. The pure wine is seldom allowed to be exported, although good and enduring, since by this doctoring there is an equality of class established that defies seasons or bad crops. The grapes are gathered when mature almost to shrivelling. They are from the *bastardo*, *sousao*, and *alvarelhao* vines. The fruit is trodden with the stalks, and remains during the fermentation, which continues about seventy hours, in vats

containing from ten to twenty pipes each, and while fermenting, brandy is added. The wine is racked in February, and sent to the company's or merchant's cellars in Oporto. More brandy is added to the wine intended for exportation, and again in a year, when shipped, more is thrown into a wine having in its natural state, on the average, amply sufficient alcohol to insure endurance with common care. It now carries a strong odor of brandy, and must remain a dozen years until the wine, or rather brandy-wine, is sufficiently subdued in alcohol to be drunk, when it bears little resemblance to the genuine wine, having become dull, and its freshness and aroma having disappeared. The consequence of the delay often is, that while ameliorating the extractive and coloring matter of the original, if not of the elderberry, becomes deposited, the wine tawny, and the flavor without a trace of the real unadulterated article. The perverseness of usage is become in a century so much in harmony, on the part of the consumer, with the merchant's notions of brandy being necessary to preserve a wine with sufficient alcohol by nature, that a genuine and honest port wine would now be regarded as worth little, on the plea of coldness, except to real connoisseurs. At first, in 1730, only about two gallons were added to a pipe. In 1754 the practice was styled *diabolical* of checking the fermentation in this mode of *fretting* in spirit, which it was fondly imagined immediately assimilated with the natural alcohol of the wine. The Portuguese charged the English at Oporto with commencing this base practice, and making wine seem *like liquid fire in the stomach*. It is observed by one authority that, in preparing these wines, it resembled throwing into one large vat all the red wines of a country of different growths, to produce an immense quantity of second-class wine. There are excellent wines thus mismanaged. The Collares port, Bucellas, Lisbon, and other wines made in the customary manner, bespeak that there is no fault except in the management. One wine-grower purchased elderberries a few years ago to the extent of four hundred pounds in a season; and one hundred and twenty pipes of adulterated must have in one year been landed in London from Oporto, to mingle with Portugal red wine in England, and doctor or strengthen what was too weak. Science can discover nothing worthy of record in the manipulation of the Oporto wines.

The vines of Madeira, now nearly destroyed by the *oidium*, or wine disease, were a remarkably fine class. They were planted in a volcanic soil, a mixture of red and yellow tufa, called *sabro* and *pedro molle*. A light clayey earth and volcanic cinders were intermingled. The husbandry was rude; the vines planted in trellises. The vintage took place in September, and the wine of the highest quality, called *pingo*, was that which flowed from the treading alone. The wine was pressed to the fourth pressing in a trough-press, with a lever like that of a cider press. The grapes were sorted and the *mosto*, or must, fermented in pipes. Gypsum was sprinkled on the grapes. The must was agitated during the fermentation, which exceeded forty days in duration. The wine was mellowed in stoves, kept at a temperature of 80° or 90°. A voyage to the East or West Indies was always preferable for

ripening the wine, when it could be accomplished. There was once a very agreeable cordial wine, made in Madeira, by checking the fermentation and adding brandy to the must. The *sercial* is the product of the hock grape, never drank under seven years old, and then not in perfection. There were once three kinds of malmsey, from as many different kinds of grapes, in these islands. That from the cadel grape was the best. The tinto resembled new Burgundy, but was less harsh; it was drank under three years old, at which age it lost its color, and took that of old Madeira. It had an agreeable aroma. Wines of Madeira were sometimes ripened by plunging them into a trench of fermenting horse dung. The bottles were corked, and thus the wine attained, in a few months, the maturity of a voyage at sea. This, however, may be doubted; because, at sea, not only a particular temperature, but a considerable agitation is kept up. A pipe of Madeira, attached to the beam of a steam-engine, in the warm engine-house, is said to have produced the effect desired. Madeira is, or rather was, in perfection in twenty years. The vine disease has suddenly ruined this far-famed wine, and the unfortunate people of the island that produced it. A very fine sample of this wine the Editor received from Mr. J. R. HUTTON of Liverpool—a nutty flavor, and yielded 15.69 per cent. of alcohol.

The wines of Spain are quite distinct from those of Portugal, as well as of France. Many of them are superior of their class, and of the white wines in particular; they constitute the largest quantity of any single foreign wine, red or white, entered in England for home consumption. The wines of Spain, except those of Andalusia, in which much British capital is invested, are carelessly made; but their firmness, just alcohol, resistance to what would ruin very delicate growths in the North, arising from a warm and genial climate, prevent their merits from passing unappreciated. The fine red wine of La Mancha, the Val de Penas, was, until recently, carried about only in pitched skins on the backs of mules. The great exports of wine are from Cadiz and Malaga. The sherry is made near the town of Xeres de la Frontera, nine miles from Port St. Mary's, across the harbor of Cadiz. The grapes are left on the tree until they are shrivelled by the sun's heat, and when plucked remain exposed to it some time before they are pressed. The fermentation is generally left to take care of itself, with all the scum it forms; and yet the wine is so fine that very rarely mischief occurs to it. Racked after the vintage, and constantly under the eyes of the agents or principals of foreign houses, resident on the spot, the management is carefully scrutinized. The grapes here are sprinkled with powdered gypsum, once locally termed *giesso* or *jess*. The must ferments in the cask left entirely to itself. It is racked in March. The casks are left open in all temperatures, and sometimes in the open air without ill effect. A good cellar, so named in France or the North, is not thought of moment here. While fermenting, the bungs are so open as to allow the easy escape of the carbonic gas. Ropiness, dreaded elsewhere under such treatment, is very rarely observed. The natural color of the pure wine is pale; the colored are from a

blending with a dark wine called *arropé*, made by boiling down six butts of must to one, keeping the liquid continually stirred and the surface skimmed, avoiding the accident of burning, on which account the process is slowly conducted. When thick enough, the fire is gradually withdrawn, so that the fluid may cool without any injury from chill. It is then mingled in different proportions with the pale wines, thus constituting colored and brown sherry. Nothing foreign is ever mingled with these wines, except a couple of bottles of very good brandy upon their exportation. The sherry, denominated *amontillado*, is a drier wine than the common sherry, and is often the result of accident. To this wine no addition but of its own class can be made without spoiling, not even a glass of brandy. A sample of this pure wine the Editor received from the highly respectable house of Messrs. CHILLINGWORTH and SON of London. It had a superb flavor, and only contained 11·50 per cent. of alcohol—proving it to be a pure wine. Of a hundred butts from the same vineyard, some will be *amontillado* without it being possible to discover the cause. Thus the constituent parts in *amontillado*, if supposed exactly balanced, raised the question, Why should this occur in a small portion only of a larger quantity? When it is made, the grapes are plucked a week or two before those for the other wine, but the treatment is just the same. The wines that pass for sherry in England in taverns, are generally made-up wines, or good mingled with inferior or low wines. Another species of wine which may come under the sherry denomination is that called *Manzanilla*—light, delicate, and straw-colored; it is not always liked at first. It derives its name, some say, from a village near Seville, and as others suppose, from *Manzanilla*, a small apple. Neither surmise is correct. *Manzanilla* is the camomile, and there is something of the taste of that plant in its flavor. It is delicate and will admit of no foreign mixture. The dryness shows that the glucose and vegetal extract are well balanced in its fermentation. It is produced from the *Rustan* grape. The wines of Malaga are of ancient date, and the vines are grown near sugar canes, the only spot in Europe where the latter are found. The *bastardo* grape makes the sweet wine. The must is conveyed from the press, half fermented, to the merchants' stores in sheepskins, and the wines are sent to all parts of the world unbranded, except to England. The mountain wine is made in Malaga, and one species is called wine of pears, because that fruit is steeped in it. There is also a cherry wine, called *guindas*, made there. It is much flavored with the cherries. There are many excellent wines in the interior of Spain, but made unpalatable from bad management in the fermentation, exemplifying the Spanish proverb—*To cry wine and sell vinegar*.

The dry wines of Xeres and Malaga, as well as those of Teneriffe, were formerly called *sacks*, and the sweet also. In 1598, in Hakhyt, it is stated by one who resided eight years at Teneriffe, that it produced three kinds of wine—Canary, Malvasia, and Verdone, which may all go under the denomination of *sack*. The wine of different ages is mingled in Andalusia, the newest with old of the purest quality.

The wines of Andalusia are rarely sulphured, from

fear of the taste remaining, and on account of English prejudices. Some Englishmen complained of the taste where sulphur had never been used. Here the stalks, and often not even the skins of the grapes, are suffered to ferment in the must. The wines are white, and color is not wanted. In France the stalks are left in the must according to the nature of the season; if fine they remain. In Spain the glucose abounds in the grape; and were it not for the practice of leaving the scum on the wine, and even returning it under the idea of supporting the wine, none would ever become acid. The system of large vats, so friendly to a beneficial fermentation, has not been tried there. Nor is it necessary; for in their present state they enter into the largest consumption in the English market. The better wines of Southern Spain yield nearly a fifth part of alcohol on distillation, and the quality so returned is excellent, and only inferior to the best of France. The *tintilla* wine of Rota is a red of Andalusia, generally taken as a cordial from its extreme richness. In Alicante a wine is made from the same kind of grape, which holds much tannin, precipitating a species of animal gelatin. It is of an orange-red color, rough, and somewhat bitter. In Catalonia the wines are generally good, and of the red species. Vinaroza and Benicarlo produce good red wines, much of which passes for port in England, either mingled with it or flavored, so as to secure the similitude. This wine is of a wholesome quality. The malmsey of Sitges is white. In Arragon, the wine of Carinena is the best. A muscadine named *Fuençaral*, is made near Madrid, and a fine dessert wine at Peralta in Navarre.

The wines of Spain have the ascendancy in England, perhaps from their freedom from acidity, owing in part to their treatment in the vat with gypsum, to which must be added their own natural tendency and strength, as seen on their exposure to the atmosphere under circumstances in which the wines of other countries would run rapidly into the acetous state. Wines which contain much of the gluten, are more susceptible of the acetous fermentation than those in which it is more sparingly dispensed; and the latter is the case with the wines of the Xeres district, in which little or none remains after fermentation, without half the trouble in racking and fining which is bestowed on other wines. There can be no doubt, this refers to the white wines of that part of Spain alone when the spirituous fermentation has ceased. The little brandy added, and often none at all, to the best wines of Xeres, as is evidenced in the beautiful sample of Messrs. CHILLINGWORTH above referred to, shows how well their constituent parts are adapted for preservation, compared with some ports and oftentimes their twenty gallons of artificial brandy. It is only to the meagre wines of the country—mingled with a little of the good, and called *low sherries*—that brandy is added, to render the wine more agreeable to the corrupted taste of the English public, which is thus to be satisfied with brandy and wine in a state of mixture, in place of brandy and water. The intemperate use of pure wine when indulged, is never followed by those disorders so common and fatal in the use of the favorite dull fiery wines of the generality of persons in England, particularly in the class called hepatic affections. Brisk,

lively, natural wine, is totally distinct in its action on the human frame from that of the brandy wines medicated for a perverted taste. The effect of pure wine in excess is transient; of brandied wine it need not be detailed. The Editor is convinced, from investigations and analyses, that there is no more *necessity* to add brandy to port than sulphuric acid to vinegar. If the liquid be well fermented, sound, and good, any addition is pernicious and wicked.

There is no just ground for believing that brandy will prevent acetous fermentation, although the common notion is that it will do so. It is incredible how far custom goes in effecting error, and preventing its correction, often indeed irremediably. A merchant of good sense desired to have sent him, even if smuggled out of Oporto, half a dozen pipes of port-wine without a drop of brandy. His correspondent would only send him one in reply to the order, being certain *that without brandy it would not keep*. The wine came and remained good in the cellar for years till drunk out. The Oporto merchant did not know, that for forty or fifty years after the Northern treaty of 1703, little or no brandy was put into a wine of a very full body, nor that Sir EDWARD BARRY complained in 1773 of these wines becoming too hot. It was not until the end of the last century that they were so fully deluged in artificial spirit—introduced at first under the idea of their preservation, and continued, perhaps increased, by fevered stomachs, which called for deep colored, sweet, and strong; in other words, for more elderberry, sugar, and alcohol.

Brandy in a small quantity will not stop the acetous fermentation in vinegar, for it becomes itself acetified, and makes the vinegar stronger. That one-seventeenth part alcohol should succeed in so doing, as some experimentalists aver, is met by other facts; for acetous fermentation is very easily produced in wine containing an eighth part of alcohol. It is still possible that alcohol added in a sufficient quantity may suspend or retard the fermentation, owing, perhaps, to its not mixing with the natural alcohol of the wine. Chemistry has not yet made this point clear; but it would seem that the general notion of vinous preservation through alcohol, unless in a ruinous quantity, as it is applied in port, sometimes to more than a fifth of its bulk, is very erroneous. The Editor has found port sold in some of the hotels with *thirty-five* per cent. of brandy!

The fact is, that the usage at first, from whatever cause, gave a desire for strong wine in England; and there was the advantage that the growths of bad and good years flung into large vats, and well mingled with brandy, gave a product of that middle-class wine artificially so made, which paid better than a little choice at a high price, and a good deal at a very low figure. It must be observed, too, that in most Northern countries, except France and those yet more to the South, there is a continued craving after alcoholic strength. This has been the case in all ages of the world. The Englishman has his wine medicated until spoiled with brandy; the Persians infuse poppies and similar things for the same end. There is ever a craving for increased stimulants, which, not found in the wine itself, must be added. The Greeks and Romans medicated

their wines, or rather perfumed them with various substances. The holy scriptures have left evidence of this, even in the earliest times of the Jews. The alcohol in wine placed there by nature seems to have its parts separated, and to be rendered comparatively innoxious compared to that added unnaturally; and, in the former case, will not readily intoxicate like alcohol mingled with water, milk, and similar liquids. The Jews had no knowledge of alcohol or the still, and endeavored to render their wines more stimulating by their deterioration, as is done at present another way. They had a general term for fermented liquids of all kinds—*shekhar*; but the words, *strong drink* or *mixed wine* are denounced, meaning wine with spices, and stimulating aromatic drugs. *Jahin* or *Yayin*—the *j* is pronounced as *t*—is the term for wine in general; *sobhe* is sometimes used figuratively for the same liquor, and *tirosk* for new wine. But *shekhar* means strong and medicated wine, of which honey was one ingredient, as well as spices and herbs. In the time of AUGUSTUS CÆSAR honey was mingled with his wine, and exposed to the sun, perhaps fermented in it; and as honey contains grape-sugar, it would necessarily strengthen the alcoholic principle, if there remained any gluten, for the emperor could drink no more than a pint of it at a time. Alcohol is formed by nature in every human stomach to a certain extent, according to an eminent chemist, and so far must be congenial to it. The reasonable use of natural wine is often highly advantageous. Discoveries in relation to the combination of alcohol with wine are yet to be made, but it remains certain that it is one of the vinous elementary constituents. Medical men will designate the difference between the effect of wine with its alcohol on the human economy, and the effect of alcohol combined with water. The ebriety produced by champagne in which carbonic gas and alcohol are combined, and that produced by pure claret or chambertin with port and madeira, are obvious to all who move in society where good wines are taken. The effects so lively and airy of the one, with the dull sedative state produced by the last, a blunted quiescent state not easily disturbed, but when disturbed not easily appeasable—indicate different effects from causes, no satisfactory definition of which has yet been obtained.

There has been much dispute regarding the alcoholic strength of wines. There is no reason whatever to dissent from BRANDE'S analysis of a considerable variety, made with great care, and there is little difficulty in making the test correctly enough; but the utility is only comparative, because the particular wine to which the test is applied must be taken for itself alone, according to the nature and produce of the grape for the year of the vintage, and not for a succession of years, nor for the same sorts generally; and the like holds good with all the constituent parts, and those slight traces of foreign substances, from differences of soil and plant, and little more, continually perceptible in wines. The same vines for two successive years will not bear fruit so exactly similar, as that some difference shall not be detected in the wine, and in the different proportions of its alcohol. The nature of the season in the same vineyard, and often under similar circumstances, will cause unaccountable changes. A warm year causes the

saccharine principle to be abundant, and, yielding more alcohol, gives a stronger wine, as is evidenced upon distillation. Nor is this natural effect more an impediment to classing wines by their alcoholic strength, than that of throwing in brandy, as in Portugal, during fermentation. By the wine being artificially brandied is prevented an accurate knowledge of its alcoholic strength, in the kind most commonly used in the British islands, as no two samples can be expected to show the same result. Thus it arose that the analysis of Dr. BRANDE was wrongfully censured, because it did not appear to be exactly what everybody supposed.

The Editor is of opinion that no port wine contains naturally more than fifteen per cent. of spirit—four or five per cent. are afterwards added to insure the wine keeping for years, in which time the artificial spirit becomes perfectly blended and mellowed in the wine.

The simplest method of ascertaining the amount of alcohol contained in wine is to distil the spirit from the wine, determining its specific gravity and quantity, and compare it with the quantity of wine taken; of course one of the first things to be considered, is how much wine to distil. The Editor takes generally one-third, and determines the alcoholic contents from it. If, for example, in the distillate thirty-three parts out of a hundred are composed of alcohol, the quantity of alcohol in the wine will be 11 per cent. for $\frac{33}{3} = 11$.

In the case of strong wines it is advisable to distil even more than a third, especially if a glass retort and water bath are used. Let the distillation be continued till at least half has passed over. If the density of the distillate is such as to yield twenty-five per cent. of alcohol, then $\frac{25}{2} = 12.5$ per cent. of alcohol.

In strong new wines, undecomposed sugar and vegetal extractive matter may cause the evolution of more alcohol during the insensible fermentation. It may be presumed, notwithstanding, that if the quantity of alcohol in any wine exceed twenty per cent. it has been added artificially. All bottled wines, which improve at all, become sweeter, and old wines always appear to have gained in sugar. A very generous wine of the Drôme, in France, will afford a third of its weight in the brandy of commerce; in the department of the Herault there will not be more than a fourth part; in the Côte d'Or about an eighth of what is called prime brandy; in the department of the Charente, a still, charged with two hundred and forty litres of wine, yields from twenty-four to twenty-six of spirit, or about a tenth of the volume of the wine, and a little more in quantity of the second-class spirit; in the department of the Gard, from the same quantity of wine, forty litres of prime spirit, and about the same quantity of the second class. From these products it is easy to approximate to correctness in regard to the amount of spirit in wine, and thus it is seen that one-third spirit is given in first and second brandy of the Gard, while there is often a third distillation, which is not included.

In France it is found necessary to accommodate the Northern palate, by adding ten per cent. to the wines supplied to that part of Europe.

A tale, that BRANDE had only tested adulterated

wines palmed off upon him for genuine, was as silly as spiteful. Dr. BRANDE took the wines as he found them in the hands of the merchant, in a state awaiting consumption; and no rival examination showed a greater difference than might be expected to exist on all similar trials. The reader must bear in mind that it is nearly half a century since Professor BRANDE analysed the wines referred to. The Editor has always considered the per centage of alcohol given in genuine port to be too high, and this seems to be corroborated by the fact that samples of port, vintages 1820—1834, *et cetera*, kindly forwarded to him by Messrs. CHILLINGWORTH for experimental purposes, never gave more than *eighteen per cent. of pure spirit*. The 1820 had a specific gravity of .9945, and the distillate .9740 = 18.01 of alcohol; and the 1834 had a density of 1.0163, and the distillate .9723 = 18.99 of alcohol. Extractive matter in 1820 was 5.140, and in the 1834, 5.976 per cent. There is too frequently a disposition prevalent to cavil at scientific men and their statements because they are novel, or do not chime in with preconceived notions. The nature of the combination of the natural alcohol with wines is not now understood, but its effects just noted are undeniable. This combination cannot be supposed to be any other than one of those secrets, the discovery of which science will one day lay open. Annexed are the results of BRANDE, PROUT, and others, as to the alcohol contained in the well-known wines in common usage.

REDDING has given an analysis in another form, as follows; but has not stated his authority:—

	Absolute Alcohol.	
	Ounces.	Drachms.
Port, in bottle of 26 oz., seven years in glass, ..	2	7
Do. 25½ oz. one year in bottle, two in wood, ..	2	6
Pale sherry, 25 oz., three years old,	2	4
Another specimen,	2	7
Madeira, 25½ oz., two years old,	2	5
Cape, 25 oz., one year old,	2	8
Old hock, 21 oz.,	1	0
Brandy, 24 oz.,	10	0
Rum, 24½ oz.,	9	8

MULDER, who has had great experience in the analyses of wines and spirits, states that alcohol varied as follows:—

	Per cent.	Per cent. by measure.
Port,	20.70	to 23.20
Sherry,	15.40	24.70
Madeira,	19.00	19.70
Marsala,	19.90	21.10
Claret,	9.10	11.10
Burgundy,	10.10	13.20
Rhine wine,	9.50	13.00
Moselle,	8.70	9.40
Champagne,	14.10	14.80
Brandy,	52.40	53.80

Eighteen per cent. alcohol by weight are equal to about twenty per cent. by volume.

The wines of Palestine, Syria, and Asia Minor vary much in alcoholic strength. Those analyzed by Professor HITCHCOCK of Amherst College, United States of America, contained from ten to eighteen per cent. of alcohol, or nearly as much as the European wines, except those of Oporto, Madeira, and Sicily, or the low wines of Spain that are brandied.

Of late years Australia has become rather prominent as a wine-producing country. The Editor's brother, Mr. FREDERIC MUSPRATT, who has resided there for some years, writes as follows:—

Wine has been made in Australia during the last thirty years, but has not been known in the towns till within the last ten years, owing to the great demand for it in the country. The vine flourishes more or less in all these latitudes, but the climate of New South Wales must be admitted to be the best adapted for wine-growing, and vineyards are established on the banks of the Hawkesbury, the Nepean, the Hunter, the Williams, and the Paterson, which are capable of being greatly augmented, to meet any demand there may be made for wine; and a rapidly increasing population will doubtless hasten their extension. The quantity of wine produced in 1857 was about three hundred thousand gallons.

The wines best known in Sydney and Melbourne are Irrawang, Tomago, Caewarra, Camden Park, Kinross, Kaludah, Porphyry, Tanilba, Wivenhoe, *et cetera*, and the *crû*—characteristic flavor—of the different varieties is as marked as is that of *Chateau Lafitte*, *Margaux*, or other European wines.

A Burgundy wine is best at Irrawang; a champagne at Kaludah and Caewarra; a medoc at Tomago, Kinross, and Tanilba; a hermitage at Porphyry; a muscat at Camden Park; and a Grâves at Tanilba.

The vineyards are principally worked by Germans, and the cellar-masters have learned their craft at Frankfort-on-the-Maine in Europe; so the local prejudice against colonial wine, manufactured formerly under the superintendence of squatters, who never had any experience in wine-making, is rapidly disappearing, the grape being richer in sugar than that grown on the Rhine-board. *The ordinary wine* of the country is considered generally to be superior to that of Germany. There has not been time to test, on a large scale, the capability of producing extremely fine wines, but, judging from the fact, that wine thirty years old is as rich in flavor and bouquet as wine the same age in Europe, there can be but little question as to the quality. At the Paris Exhibition of 1855, the jury, upon tasting a red wine, two years old, called it a *joli vin, beaucoup d'avenir*, and awarded it one of its highest numbers. All present expressed their surprise at the result of the examination, and highly approved of the wines. The foreman said they were perfectly astonished at the quality of the Australian wines, and were unanimous in giving them a place, for strength and flavor, between the wines of Madeira and those of the *Côte du Rhone*.

A Sydney trade-circular, in describing the wines at present in the market, says:—The wines of this colony are essentially Australian in general character. They

assimilate to the French and German wines. Some are considered by connoisseurs to resemble hock, Sauterne, claret, Burgundy, and the like, but no attempt is made to imitate these or any other wines. Of course, the vines are in great variety, but, from whatever description of grapes they are made, each vineyard has a peculiar local character, distinguishable by vinists. The Camden wines will first be noticed. These are of three sorts, namely—white, which resembles the Rhenish wine; red, which approaches Burgundy in taste; and muscat, rather like the Frontignac of the Cape, malmsey, or Madeira. Now for the Irrawang wines. The white is considered like hock or Sauterne; of the red there is at present no stock; and the sparkling Muratta is a very fair champagne. Next, the Wivenhoe wines will be referred to. These are—the white Muscat, resembling hock; red, corresponding in flavor with Rhenish wines; Madeira, which is of a Frontignac description; and Reissling. There are some wines grown at Oatlands, near Paramatta—the red resembles a claret, and the white corresponds with a light French wine. Under the head of Notes and Queries in the *Spectator*, is the following:—The samples of Australian wine at the Paris Exhibition have earned special commendation. When the horticulturists of that colony shall have succeeded in extending the cultivation of the vine over the land of the dreary *Encalyptus*, one may imagine that it is destined to the nurture of a British BACCHUS, and may look forward to the importation of Australian wines; and upon its arid soil, even upon the chasm of pools that its rivers present in the summer, would be exhibited the same miracle which is to be seen in the South of Europe, the juicy grape growing upon a parched soil, and for a season would be clothed with the loveliest foliage under the sun. Fancy the change of character that must come over the British stock habitually living in such scenes, under such a sun, with such a diet. It will be an experiment somewhat such as the world might have witnessed had the Saxon been planted in Italy. These queries are curious, as indicating the notions of the untravelled; but parties are daily getting more accurate knowledge as to the actual capabilities of the British Colonies.

The vineyards in the neighborhood of Adelaide, South Australia, are rapidly extending, and on the banks of the Murray and Murrumbidgee; the wines that are grown there will bear comparison with those of other lands. The only drawback to a rapid increase in the wines made in Australia lies in the dearthness of labor; but as all the farmers along the thousands of miles of river banks are all planting their small vineyards—which may be tended by their wives and children—and as merchants, who will buy the juice and await its ripening, are establishing themselves at convenient places, there is every prospect of the trade becoming greatly enlarged.

In the ripening of wines Australia possesses an advantage over Europe. As there is no winter there, so is there no check to the fermentation after the juice has been removed from the vats to the casks. This check to the fermentation in Europe is the cause of much wine *fouling*, and is the mother of many of the

so called *sicknesses in wines*. This is a source of great anxiety to many of the large European *vignerons*. On account of the hot winds in Australia, the vines are pruned low; and as this method, combined with a hot sun, causes more *must* to be in the grape than is usual in Europe, it is found that the fermenting juice will, as a rule, bear a large quantity of *stalk*; the consequence is, that the elements of bouquet are much more prominent than with wines of the same strength in Europe.

The foregoing remarks are well worthy of attention. Good and sound wines doubtless have been made in Australia; but the Editor is not so certain whether the English will ever admit any wine produced in the colonies to be equal in that beautiful aroma—which science has not yet been able positively to assert what it is—and flavor belonging to the first-class wines of Europe—Johannisberg, Sauterne, Rudesheimer, Liebfraumilch, *et cetera*.

In 1852, specimens furnished to Baron LIEBIG will explain the result of an attempt at wine-making in that colony. This wine, principally from the grape called the pineau noir and gris, carried a specific gravity of 0.992, and gave 16.20 per cent. of alcohol; 0.505 of free acid; 3.265 of dry residue; and 0.498 of incombustible ashy constituents. Another species of white wine grown at Irrawang had a specific gravity of 0.94; gave out thirteen per cent. of alcohol; 0.66 of free acid; 3.313 of dry residue, chiefly saccharine; and 0.563 per cent. of ashy constituents—proportions met with in some of the European wines, particularly the German. LIEBIG also analyzed other wines of Australia, and among them one obtained from the white muscat grape, which gave 19.53 per cent. of alcohol and 0.64 of free acid.

The wines of South America have not been analyzed. They are scarcely known in Europe. There is, however, a red wine made at Chili which is much liked by Frenchmen, and is considered a very fine *vin ordinaire*; instances being known of French men-of-war putting in to Chili and stocking their vessels with hogsheads of it.

The difference in the intoxicating effect of wine, and brandy and water, it has been asserted does not exist. Professor BECK, taking brandy at 53.39 of alcohol, calculated strong Madeira at 48.26; weaker Madeira, 36.14; port, average, 42.33; Bucellas, 35.21; sherry, 33.75; Sauterne, 24.34; claret, 21.38. He is of opinion that the difference between wine and brandy and water is more fanciful than real. New wine is more intoxicating than old, although the latter is more spirituous; and, according to SOEMMERING, loses of its aqueous parts by age. BRANDE, with good reason, supposes that when brandy and water are allowed a sufficient time for combination, the intoxicating power may not be more than that of wine containing an equivalent of brandy. Thus the effect of brandy and water arises from their imperfect union. On the other hand, it is certain, that the evil effects of the two, when taken in excess, upon the animal system are very different. Fine pale cognac—HENNESSY or RENAULT'S—with water, is often prescribed for invalids, and with great success. The Editor is of opinion that such a beverage taken constantly is less injurious than heavy, and especially drugged wines.

In some places in the North of Europe wine has been exposed to severe frost, under the idea of imparting strength to it, by drawing off the unfrozen portion. In the Augustan age, when the Euxine sea used to be frozen over, the wine in the casks, it is said, was cut with hatchets. Mr. PARKES experimented on wine exposed to 22° below the freezing point. He could discover no difference in taste between the fluid frozen and unfrozen, and thought the unfrozen the more rapid of the two. Of five hundred and sixty grains of port wine, five hundred and forty remained liquid; and of sherry two hundred and eighty-five grains were frozen, and one thousand and fifty-six remained in a fluid state—a result not in accordance with the experience of the colder wine countries of Europe.

The various matters discoverable in wine are not all found in the same growths. Less or more in some, and none at all in other kinds, with ever varying quantities, render analysis only good in relation to single specimens, and of no service in laying down a general rule for all. Thus water, sugar, alcohol, gum, extractive and nitrogenous matter, or albumen; the bitartrate of potassa, sulphate of potassa, chlorides of potassium and sodium, and in red wine coloring matter, and tannin from the stalks; carbonic acid in sparkling wine, and a perfume or bouquet, a species of ether—*enanthic*, *acetic*, *et cetera*—found in the fermentation, and citric acid—a mere trace of the latter—have been found in wine. Malic and gallic acid were thought at one time, with tartar and sugar, adding the gluten, to be almost the entire of the principles discoverable, and that all wines were the same in this respect; but science has undeceived the world upon this point. The amount of sugar in some sweet wines is full thirty per cent. according to PROUST. White wines are more perfect than red, and will endure longer; perhaps arising from the absence of the acid taken up by gypsum in the making, which cannot be used in red wines. The color of the red wines sometimes approaches to black from intensity. Indeed, a powerful wine in France carries the name of the Black wine of Cahors, generally used for strengthening weak-bodied or light-colored wines. Port wine of the vintage 1812, and that of 1820—CHILLINGWORTH—are nearly black, although upwards of forty years old. From pink to black in red exist, and from water to a deep golden hue in white wines, and even a green color in the wines of Cotnar. Amber and brown in different shades are to be met with, but no merit in regard to the quality of the wine attaches to the hue, however agreeable one more than another may be to the vision. Perhaps the clarets—so named from the French *clair*et, which, however, attaches to a different species—hold the middle place in regard to color, between the light red and black. The coloring matter in red wines may be obtained by an exposure of the bottle to the sun's rays, when it will fall in flakes; the taste of the wine remains unaltered. Before adding lime water the coloring matter is precipitated with the insoluble salt formed by the wine and acid of the wine in union. The finer wines are generally those in which the color is most attended to by the maker, and the rivalry in this respect is considerable. It is a matter in which preju-

dice operates. Many people cannot be persuaded that a pure red wine, of a light color, may be far superior as a wine in every good quality to one deeply colored, even when perhaps, as in port wine, it is aided by the elderberry.

When red wines lose color on the Continent they are said to be *rancio*, rusty; in England tawny. The coloring matter deepens on the deposit of tartar, and the tawny hue arises from age. Heat, too, will injure the color, which is thus not necessary to the flavor of the wine, being no way dependent upon it. Carbonate of potassa, sometimes formed in wine, injures both the color and flavor. It arises from the decomposition of the tartar, and in France is called the *tornure*. A little tartaric acid being added, the potassa forms cream of tartar, depositing crystals.

Wines grow darker as they ameliorate up to a certain point, but this is not uniformly the case. The alcohol in the wine, diminishing by evaporation, has no relation to this change; indeed, it is probable, that the aqueous portion evaporates rather than the spirituous. The specific gravity of wine increases under those circumstances. Many affirm that the alcohol in bottled wine increases by age; MULDER asserts that such a statement is thoroughly false, the formation of alcohol in the bottles being impossible. SOEMMERING discovered, that there were substances which permitted the aqueous portion of wine to escape more freely than the alcoholic. Equal parts of alcohol and water were placed in a glass vessel, and the mouth closed with a piece of bladder.—See ALCOHOL. It was observed, that under the circumstances more water was lost than alcohol, but when the temperature was raised to 62° it passed through the bladder unchanged. From this, and other experiments, SOEMMERING took the idea of ameliorating wine by exposing it to a similar process. He, in consequence, covered a glass vessel full of wine with a bladder, and suffered it to remain eighty-one days aside in a warm dry room. During that time one-half had evaporated, and the residue had acquired a more spirituous, mellow, and agreeable flavor. The color was deepened, a film had formed over the wine, and a deposit of crystals had taken place at the bottom of the glass. The proportion of alcohol had doubled from 4.0 to 8.0. A repetition of the experiment gave the same result, and thus a more rapid mode of ameliorating wine was discovered, than keeping it in wood, to effect the disengagement of the alcohol and water by time. Hence the transportation of wines to a tropical climate and home again, exposing the wine to aqueous evaporation, easily accounted for the beneficial effect, and the same with heat artificially applied. Wines thus exposed, too, deposit rapidly. Thus it is a common trick with port wine-mixers to place the bottles in water, carry it to the boiling point, and then, taking them out and placing them in the cellar, *the crust so admired by the ignorant in port wine is immediately formed*. It has been advanced, in consequence of the foregoing discovery, that the amelioration of wines in the wood is effected mainly by the disengagement of some of their water—the alcohol being retained, or a smaller proportion of alcohol than water being evaporated, the rest of the wine becomes more

concentrated—and that for this purpose vessels are most desirable which will retain the alcoholic and permit the aqueous particles to escape. Wine is observed to evaporate more rapidly in chestnut casks than in those of oak or similar close-grained timber. To such an extent is this evaporation carried in chestnut casks, that the French have prohibited the exportation of brandy in any but what are made of oak. Hence it may be conjectured, that the larger the surface of the liquor exposed the more rapid will be the evaporation; and that as the fermentation is quickened by the larger bulk in action, so it is with vinous amelioration. There is probably a limit here, which it would be very desirable to ascertain, but to which discovery no approximation has yet taken place. The Germans of late years, as they have discovered that, beyond the point of maturity in wine, the long keeping once thought of so much importance is not really of any great moment, seem also to have discovered that tuns of a moderate capacity are fully as advantageous as the gigantic vessels, by their fathers deemed of so much moment, for mellowing their Rhine wines.

Wine is continually sophisticated and adulterated, especially such as is of a coarse nature, having no obvious standard of taste. Of such wines port is, from the common usage, and the different flavors imparted to the wines of that name, the most abused. It is clear that a wine of any given species, if pure, will differ very little more in flavor in any season than the strength or weakness of the must will occasion. The main characteristics of the wine will be present. In a first-class Burgundy wine, for example, it will always be possible to distinguish that the wine is the growth of the country assigned, and no other wines will be drank in its place that are not of the same order. This would be the case with all sound good growths, and with the wines of Oporto as well, had they not been continually deprived of their natural character by mingling, coloring, and brandy adulteration. A house—IRELAND and Company of Bristol—was renowned for its excellent Bristol port wine, and a handsome fortune realized. All at once, on the breaking out of the French revolutionary war, Bristol ports were no longer to be had, and IRELAND and Company wound up their affairs, because they could no more obtain the wines of the South of France, for which they were celebrated as port-wine merchants, not a cask of their wines having ever been in Portugal. Now, such a deception could not be practised with Burgundy, champagne, or the finer wines of France.

The Editor has repeatedly had *English-made port* sent to him, but the imitation in no instance deceived him. The *taste* was sufficient to detect the imposition.

The mingling of inferior wines with superior, or with brandy, is not the sophistication for which the chemical professor is so much required to confer a boon upon the public, as in detecting extraneous substances of no vinous character at all. To brandy intermixed with wine, and which never blends with it as the natural alcohol of the wine does, are owing, in many cases, the liver complaints of the wine drinkers in England—a disease rare in wine countries.

The alcohol in wine may be ascertained by adding

one part of a concentrated solution of subacetate of lead to eight of wine by measurement. A precipitate is thus formed: agitate the mixture for a few minutes; pour the whole upon a filter; and then collect the fluid. This fluid consists of the spirit and water, with a portion of the lead. Now add by little and little *pure*, warm, dry subcarbonate of potassa—not the salt of tartar, and subcarbonate of potassa of commerce—which has been freed by heat from water. This must be done until the last portion remains undissolved. The spirit in the fluid being thus separated by the potassa abstracting all the water, the former will be found a stratum upon the salt. The experiment should be made in a glass tube, from half an inch to two inches in diameter, graduated into a hundred parts; and thus the quantity of spirit may be read off at sight.

To detect elderberry coloring in port and other red wines, acetate of lead is the simplest test. With pure red wine it throws down a greenish-grey precipitate. A deep blue precipitate is the result of elderberries, logwood, and bilberries. Brazil wood and red sanders are thrown down red. Lime water destroys the color imparted by beet.

WATSON in his chemical essays, as to his assertion that lead has been used in wine, is contradicted by the best French chemists, who have never been able to find a trace of its usage, and assert that it cannot be of any service. In England, among the fabricators and amenders of base wines, sugar of lead and litharge have been ignorantly applied for cleansing white wines rapidly, according to their own statements. Ignorance and vice generally travel abreast. Thus to keep wines from turning, some one of the vulgar receipts has proved a very harmless one—Put in fair water a pound of lead which has been melted; then into the cask, pretty warm, and stop it close! Oyster-shell lime has been used for the same purpose, an ounce to two gallons of the wine. Cochineal, to the extent of half an ounce dissolved in wine or brandy, is one means used to improve color; and for port wine the compound called *geropiga* made in Portugal, and imported into England openly, as a *liqueur* solely for sophisticating port wine. Port and claret are rendered rough by baking two quarts of sloes in a gentle oven, or over a slow fire, until their moisture is given out. The fruit is squeezed, and a pint of the liquid is applied to thirty or forty gallons of the wine.

Substances native, such as genuine must, wine, alcohol, or sirup—that is, boiled wine—can alone be tolerated in mixing. All besides is more or less a fraud. The object of mixing litharge, potassa, and tartrate of potassa, is to arrest bad flavor and temper sharpness in new wine. Some substances for color, sugar and honey to sweeten, spices to improve the flavor, and perry and water to increase the volume, are complained of in France. There is a commission there of able chemists, who examine samples of wine with great care. First, as to litharge—a poison—no one instance of its use has ever been detected. In 1824 a petition was presented to the French chamber of deputies, making such a charge against the wine merchants generally, that the public were alarmed, and an inquiry was instituted. The result was, that no single instance

of the employment of litharge could be substantiated—that, chemically speaking, litharge was a substance which, from experiment, contributed more to the deterioration than the preservation of the wine, and the merchants had no interest in its use. The petition was rejected as without foundation. In analyses of the wine for fifty-five years, the French council of health never met with the traces of such a substance in wine. They only stated that they had to complain, that too much water and often perry had been mingled to increase the volume of the wine. Sirup of dried raisins had been used with colored water, and fermented and sold to imitate the wines consumed in cabarets, but never any deleterious substances, under countless analyses. M. JULLEN experimented upon this substance in 1824. In a litre of musk in a state of acetous fermentation, one gramme and a half of powdered litharge was mingled and agitated several times for twenty-four hours, and then suffered to rest. The wine was tasted two days afterwards, and found as acid as at first, and unchanged in color. It was then filtered, and sulphuric acid being added, the white precipitate of the sulphate of lead was scarcely perceptible; but the sulphide of potassium, in another part of the liquid, caused a precipitate of the color of the lees of the wine. The result of four analyses was, that litharge did not deprive wine of its acidity, and contributed more to its decomposition than preservation; that in any considerable quantity it destroyed it, and that in a small quantity it remained in the wine in a state to be recognized with facility. If used in domestic wines, the same effect would follow. It was probable that the tartar of the wine had been mistaken for it. After all the scientific researches of foreigners into the nature of wine, they have not succeeded in detecting the quantity of perry, water, and not insalubrious ingredients, added by the dishonest dealer.

Frauds in blending wine, often too common, are not managed with substances foreign to the grape. The rinsings of brandy and rum casks, Cape wines, cider, coloring matter, and tartar, or anything which will form a basis with Benecarlos, Figueras, red Cape, mountain, tartar, gum-dragon, cider, for port; and for coloring it red sanders infused for fourteen days in spirit of wine. Port is also made with that wine, twelve gallons; spirit of wine, six; brandy, three; rough fine cider, forty-two. A strong decoction of Brazil wood and alum imitate the favorite crust. Sherry is imitated, but the low-priced wine mingled with Cape answers the end. The notion that lead helps bad wine is current in England. But little faith is to be placed in such reports, since it has not the effect ascribed to it. Sulphide of hydrogen gas will detect lead in wine, turning it deep brown or black. Alum, sometimes used for astringency, or for the purpose of brightening the color, or of clarifying newly made wine, may be detected by first decoloring the wine—if red—by means of animal charcoal, previously washed with hydrochloric acid, filtering, and evaporating the liquid to about one-third of its volume in a porcelain or platinum capsule, and refiltering. If a precipitate has been formed while concentrating; if potassa, soda, or

chloride of ammonium produces when poured into the filtrate, a white precipitate soluble with the aid of heat in excess of alkali; if carbonate of potassa or soda produces a white deposit; if nitrate of baryta or or chloride of barium produces also a white precipitate insoluble in acid, *alum is present*; or as NORMANDY further adds, a given portion of the wine may be evaporated to dryness and ignited, the residue treated with a little hydrochloric acid, evaporated to dryness and re-treated with dilute hydrochloric acid. If now the addition of caustic potassa produces a white gelatinous precipitate soluble in excess of alkali, but which is reprecipitated by chloride of ammonium, then alum is present.

Not to follow these deceptions further—the field it may be inferred is a wide one for the investigation of science, by researches into the defects of wine itself, and pointing out proper remedies—the inequality in must of the product of the grape, from so many causes, requires to be obviated; but no rule can yet be laid down by which existing evils can be certainly avoided. Among the curious facts in relation to pure wines are the character of their deposits, so varied in form and density, according to the growth of the vine and temperature of the year when the vintage occurred. Some are oily, others muddy, adhering to the side of the bottle; and some are very light, so that on the least movement they mingle with the wine. Oftentimes the same wines will make a deposit in two different forms in the same bottle, one adhering to the sides or uniting in a mass at the bottom of the wine, the other suspended in the liquor. One species of deposit resembles litharge, and no doubt caused the report of its usage. In champagne wine the deposit is called *depot-pierre*, a precipitate in the form of very fine sand, or little scaly crystals, which are the tartar naturally deposited. All wine residuums contain more or less of this substance, but it is often so enveloped in the oily or muddy parts of the precipitate that it is not apparent. It is heavier than other deposits, and when mingled with the wine does not communicate any bad taste, alters its clearness very little, and when shaking the liquor ceases it falls to the bottom. This deposit is found in the better wines, and those having it preserve their excellence a long time, and are less subject to disarrangements than the wines the residue of which floats in the liquid. In order to investigate the nature of this substance, it is dried and placed upon burning charcoal. In consuming it emits an odor of burnt tartar, and on keeping up the fire, leaves a white residue which is found to be potassa.

The choicest wines keep the longest in bottle, and deposit there so much that, in order to have the wine perfectly limpid, it is necessary to decant them with great care. It is useless to place them in different bottles for no other reason but to secure transparency, as they will soon begin to deposit anew. Unless they are to be removed to a distance, or there is a fear of their acquiring a bad taste, they should remain untouched. This operation, when necessary, is to be performed with great care. Small glass or tinned siphons have been tried for delicate French wines, but not with the desired success. Crape or gauze has its inconveniences. An

instrument called a *cannelle-aérifère*, invented by M. JULLIEN, is used for the purpose in France, as well as for chemical transfusions. For champagne more particularly it is well adapted. Wine is sometimes placed in demijohns, which hold from thirty to sixty bottles each, by which means it is well preserved; but the inconvenience of stirring up the deposit is in no way lessened on attempting to transfer their contents.

The disproportionate allowance of brandy thrown into wine is after all the great evil encountered in the wines destined for British consumption, and this is always to be detected by science. All wines of the highest class are deemed too weak and thin. The merchant imagines that it prevents acetous fermentation, and he knows that it blends all qualities into that which is most plentiful. Dr. McCULLOCH denied that it suspends acetification; Mr. CADET says, that if administered to the one-seventieth of the entire value it will do so. Alcohol is not separated by the action of heat, since it has been effected at 56°; but, however, this may be, wine to which brandy has been artificially added, affects the nervous system to a degree far greater than wine in the natural state, and chemistry has not yet been successful in discovering any theory which will account for it. The following tables show the importations of wine and the amount for home consumption for the years mentioned in the respective columns:—

TABLE OF WINE IMPORTATIONS.

Years.	Tuns. French.	Tuns. Portuguese.
1675	7,495	20

The Methuen treaty to favor Portugal at the expense of France was signed in 1703—the duty on French wine to be one-third more than on that of Portugal. A tun of wine is two pipes, four hogsheads, or two hundred and fifty gallons old measure, or two hundred and thirty-one cubic inches. From the year 1785 the returns include all sorts and quantities of wine, however small. In 1813 the records were destroyed by fire at the Custom House.

About this time the returns were made in imperial gallons, the old measures being abolished.

1810	6,521,293	1834	6,480,544	1858	6,697,146

The wine consumption, with a population of about eight or nine millions in 1787, augmented to nearly twenty millions of souls in 1851, showed little increase, in consequence of the duties on several classes of wines reaching fully to 500 per cent. That the means of purchase increased with the population, is shown by the augmented value of property assessed in 1803 = £115,351,952, and in 1843 = £181,322,202.—*James on the Wine Duties*, 1855. If, with eight or nine millions of souls, we consumed seven millions of imperial gallons, with twenty millions of population we should have consumed double that quantity, in place of no increase having taken place—spirit having been substituted.

	Imperial Gallons.	Population.
1787 to 1792	39,158,218	8,000,000
1793 to 1798	36,871,802	8,500,000
1799 to 1804	41,107,197	10,812,000
1805 to 1810	35,466,570	..
1811 to 1816	29,231,636	13,296,177
1817 to 1822	29,273,636	14,072,331
1823 to 1830 (8 years)	50,583,970	16,000,000
1831 to 1836	37,495,674	16,255,605
1837 to 1842	37,936,392	18,664,761
1843 to 1848	38,574,512	..
1849 to 1854	38,909,486	20,919,531

The consumption of wine was three and a half bottles per head from 1785 to 1794. It fell to three bottles from 1794 to 1814; and from 1814 to 1820 to two bottles. After that one and three-tenths bottle per head.

From 1786 to 1794 the Portuguese wine consumed in Great Britain, principally port, was 75·67 per cent., because there were only two-thirds of the duty paid upon the wines of Portugal that were paid on other wines. The duties were equalized in 1831, and from that time to 1854 the consumption of port diminished, until, in 1854, it was only 36·69 of the whole consumption. Spanish wines, only 16·67 in the first period, rose to 38·34 per cent.; French wines that were only 3·26 per cent., had risen in 1854 to 8·12.

Table of the proportions of different wines consumed in England, for which the Editor is indebted to Mr.

JAMES, author of the *Wine Duties considered Financially and Socially, et cetera*, 1855:—

TABLE OF PROPORTIONAL CONSUMPTION.

Years.	Colonial. Per cent.	Spanish Per cent.	Portuguese. Per cent.	French. Per cent.	Sicilian. Per cent.	Madeira. Per cent.
1849	3·87	39·16	42·36	5·03	7·11	1·14
1850	3·82	38·36	43·73	5·29	6·61	1·09
1851	3·74	40·33	40·02	7·12	6·28	1·10
1852	3·82	41·08	39·23	7·05	6·12	1·1
1853	3·92	39·58	38·87	7·79	7·55	1·02
1854	3·75	38·33	36·67	8·15	11·32	0·06
1855	3·95	40·42	35·16	7·99	10·82	0·05
1856	4·02	39·81	34·03	8·33	10·43	0·57
1857	6·05	39·43	32·72	8·83	10·62	0·05
1858	10·89	39·67	28·69	8·54	10·33	0·05

Proportion of White to Red Wines consumed.

Years.	White.	Red.
1854	52·065	47·935
1855	54·32	45·68
1856	54·31	45·69
1857	54·85	45·15
1858	59·21	40·79

Cape import at half duty.

Cape consumption.

Imperial Gallons.	Imperial Gallons.
361,605	261,564
492,087	352,330
787,753	456,214
654,118	726,314

DECREASE IN IMPORTATION, 1858, COMPARED WITH THE PREVIOUS YEAR.

Total.	Pipes.	Decrease. Pipes.
French imports	1,742	504
Portuguese imports	14,240	3,332
Spanish imports	20,078	1,114
Sicilian imports	1,900	114
Madeira and Canary	192	52
From Holland	79	32
Other places	2,339	401
British Possessions	1,427	..
Total	41,997	5,549
		2,950 { Colonial increase at half-duty deducted.
		2,599 Decrease.
		58 { Decrease mixed in bond.
Total	2,657 Pipes decreased.	

The Cape wines at half duty increased in ten years, from 3·87 to 10·89. Spanish were stationary, or with a small increase. Portuguese decreased from 42·36 to 28·69. Other wines, except Madeira, increased.

In the monetary provisions of the government for 1860, the duties were reduced upon all wines of all countries and of our own colonies from five shillings and sixpence and five per cent., to take place on January 1, 1861, on wines of the lowest alcoholic strength, or not above 18°. These to be admitted at one shilling per gallon. The wines above this alcoholic strength at two shillings, or wines "approaching 40° of proof spirit. This reduction to commence at first by a fall of duty to three shillings per gallon, from the existing five shillings and sixpence $\frac{2}{20}$.

The grocers' home made wines, free of duty, aided to supersede foreign wines in consumption, and thus injured the exchange of goods with the foreigner;

these wines or compounds having been sold at little more than the duty only on foreign wines.

The average product of wine in France is nine hundred millions of gallons; and in Paris two hundred and sixteen bottles per head are annually consumed; in Hamburg twenty-nine per head. The following table is the most authentic extant, and there is reason to think much within the real limit of the produce of the wines of Europe:—

	Gallons.
France	900,000,000
Hungary and Austria	500,000,000
Spain	220,000,000
Italy	195,000,000
German States, Prussia, Luxemburg, &c.	45,000,000
Portugal—total product	10,500,000
Sicily	3,000,000
The Azores	575,000
The Canaries	1,875,000
Cape of Good Hope 14,000 leagues } of 60 gallons	840,000
Cyprus, Commandery, Muscadines, &c.	30,000
Servia, Wallachia, &c.	170,000
Total	1,876,990,000

Greece produces four millions six hundred and forty thousand oke; Asia Minor, Syria, Palestine, Persia, and the East produce wine, as well as some parts of Southern Russia.

The following tables, from *Redding on Wines*, contain a selection out of a number of the fine growths, of the names and character of the wines produced in the principal countries in Europe. To extend the list would be useless. In France alone, there are six classes of red wine, seven of white, and five of *vins de liqueur*. There are four hundred and sixty-three red wines, two hundred and forty-three white, and nine *de liqueur*. The champagne wines alone reckon six degrees in quality:—

WINES OF THE FIRST CLASS.

FRANCE, SPAIN, HUNGARY, GERMANY, SICILY, NAPLES, AND CAPE OF GOOD HOPE.

Wines.	Country.	Place.	Character.
Romanée Conti.....	France	Côte d'Or	The first and most delicate red wines in the world, full of rich perfume, of exquisite bouquet and fine purple color; light, yet with body and spirit sufficient to render them pleasant and healthful in use.
Chambertin.....	"	"	
Richebourg.....	"	"	
Clos Vougeot.....	"	"	
Romanée St. Vivant.....	"	"	
La Tache.....	"	"	
St. Georges.....	"	"	
Corton.....	"	"	Burgundies, closely resembling the above growths in aroma, and all their other qualities.
First growths of Prémaux...	"	"	
Musigny.....	"	"	
Clos du Tart.....	"	"	
St. Jean.....	"	"	
Perrière.....	"	"	
Veroilles.....	"	"	
Morgeot.....	"	"	White, highly esteemed.
Mont Racht.....	"	"	
Lafitte.....	"	Gironde	Fine color and perfume, light, less warm than Burgundy, with a taste of the violet, and a rich purple hue.
Latour.....	"	"	
Château Margaux.....	"	"	Wines of the Rhône, darker in color than the preceding. Red Hermitage the most noted of these, of good body, and a fine flavor of the raspberry.
Haut Brion.....	"	"	
Beaume.....	"	La Drôme	
Muret.....	"	"	
Bessas, Burges, Landes.....	"	"	
Méal and Gréneux.....	"	"	
Racoule, Guionière.....	"	"	
Sillery.....	"	Marne	White, still, dry; of an amber color; generally iced for drinking.
Ay.....	"	"	
Mareuil.....	"	"	Fine effervescing wine, bright in color, slightly frothing.
Hautvilliers.....	"	"	
Piery.....	"	"	The best of the white wines of Champagne, being all of the first quality, but differing a little in color and effervescence.
Dizy.....	"	"	
Eprenay—Closet.....	"	"	Fine white wines of excellent quality, lightish brown in color, aroma most agreeable, and some of rather sweet taste.
St. Bris.....	"	Gironde	
Carbonnieux.....	"	"	
Pontac.....	"	"	
Sauterne.....	"	"	
Barsac.....	"	"	
Preignac and Beaumes.....	"	"	
Château Grillet.....	"	La Loire	Description resembles the preceding.
Hermitage.....	"	Rhône	
Rivesaltes.....	"	Pyrénées Orientales	Full of body, spirit, and perfume. The white is the finest of all white wines.
Colmar, Olwiller, Kaiserberg.....	"	Haut Rhin	
Kientzheim, Ammerschwir.....	"	"	A rich muscadine.
Hermitage de Paille.....	"	"	
Amontillado Sherry.....	Spain	Rhône	Straw wines, rich and luscious.
Schloss Johannisberger.....	Germany	Andalusia	
Lacryma Christi.....	Naples	The Rhine	A dry delicate wine.
Syracuse.....	Sicily	Naples	
Tokay Essence, and its first growths, called Tarzal, Szeghi, Zadany, Tolesva, also Erdo-Benye, Zambor, Tallya, Mada.....	Hungary	Syracuse	Ditto.
		County of Zemplin	
Cotnar.....	Moldavia	Cotnar	A fine, luscious, sweet red wine.
The Commandery.....	Cyprus	Com. D.	
Constantia.....	Africa	Cape of Good Hope	Remarkably fine red muscat.
Lagrimas.....	Spain	Malaga	

SECOND CLASS.—FRENCH.

Wines.	Place.	Character.
Verzy, Verzenay, Mailly, St. Basle, Bouzy, St. Thierry.....	Marne	Red wines of Champagne.
Vosne, Nuits, Chambolle, Volnay, Pomard, Beaune, Morey, Savigny, Meursault.....	Côte d'Or	
Olivotes, Pitoy, Perrière, Préaux .. Chainette, Migrenne.....	Yonne	Excellent red Burgundies, very little inferior to first growths.
	"	
		Good wines.

SECOND CLASS.—FRENCH.—(Continued.)

Wines.	Place.	Character.
Moulin à Vent, Torins, Chénas.....	{ Saone et Loire, Rhône Rhône }	Red.
Hermitage, second growths.....	"	Red.
Côte Rôtie.....	"	Red.
Rozan, Gorze, Léoville, Larose, Branne-Mouton, Pichon-Longue- ville, Calon.....	Gironde	Red.
Côteau Brûlé.....	Vaucluse	Red.
Jurançon, Gan.....	Basses Pyrénées	Red.
Roussillon, Bagnols, Cosperon, Col- lioure, Torémila, Terrats, Mas- deu.....	Pyrénées Orientales	Red.
Cramants, Avize, Oger, Menil.....	Marne	White Champagne wines, of good quality.
La Perrière, Combotte, Goutted d'Or, Genevrière, Charmes et Meursalt }	Côte d'Or	White Burgundies, of high repute in France.
Guebwillers, Turkeim, Wolxheim, Molsheim, and Rangen, in Belfort }	Haut Rhin Bas Rhin	Dry, white, and <i>vins de paille</i> , of good repute.

Vauvillan, Grises, Valmure, Grenouille, Vaudesir, Bourger- eau, Mont de Milieu et Chablis. }	"	Rich sweet wines, boiled wines, and malmseys, of good quality.
Pouilly and Fuissé.....	Bouches du Rhone	
Etoile, Quintignil.....		
Pujois, Ilats, Landiras, Virelade }		
St. Croix du Mont, Loupiac.... }		
St. Michel sous Condrieu.....		
Frontignan and Lunel.....		
Vins de Picardan of Marseillan and Pommerols. Vins de Ca- labria, de Malaga.....		
Roquevaire, Cassis, Ciotat. Vins Cnits.....		

SECOND AND THIRD CLASSES.—GERMAN.

RHINE AND MOSELLE.

Wines.	Place.	Character.
Johannisberger	Johannisberg	{ Grown near the Schloss Johannisberger, in the list of first growths already given. A very fine growth.
Steinberger	Rheingau	
Rüdesheimer { Berg	Rheingau, six leagues from Mayence, facing Bingen; on the hill and slope behind the houses.	Lighter than Johannisberger; fine bouquet. A highly prized wine.
{ Hinterhäuser		
Laubenheimer	Mayence district	Lighter than Johannisberger, but delicate.
Kösterich	"	Ditto.
Niersteiner	"	A good wine, with fine flavor and body.
Oestricher	Worms	Ditto.
Liebfrauenmilch	The Rhine	Hence the word hoch. The first growth is the prime hoch wine of the importer. Light, agreeable—12·08, average of spirit. Some kinds, when new, contain as much as 14·37, according to BRANDE.
Zornheimer		Choice wine, of fine flavor.
Hochheimer	{ Spire, on the } { River Mayn }	Light, agreeable, good bouquet.
Graefenberger	Rheingau	An excellent wine.
Gaubischeimer	{ Near Mayence, } { the palatinate }	Ditto.
Deidesheimer	"	An excellent wine, light and delicate.
Oppenheimer	"	Ditto.
Bodenheimer	"	Of first quality.
Nackenheim	"	Ditto.
Braunberger	{ Moselle, Treves } { district }	Ditto.
Scharzberger	"	Ditto.
Graach	"	Ditto.
Zettingen	"	Ditto.
Wehlen	"	Ditto.
Piesport	"	Ditto.
Montagne Vert	"	Second quality.
Causel and Valdrach	"	Moselle, noted for diuretic qualities.
Rinsport	{ Moselle, Witlich } { canton }	Secondary Moselle.
Bacharach	Near Mayence	Wine once in high repute.
Becherbach	Becherbach canton	Secondary Moselle.
Walporzheimer	Upon the Ahr	Called wine of the Ahr.
Rutz	On the Moselle	Considered one of the Moselle wines.
Steeg	Near Bacharach	A light Rhine wine.
Montzingen	"	Inferior light Rhine wine.
Bodendorf	Near Bonn	A secondary wine.
Affenbourg Hamen	Near Coblenz	Ditto, a Rhine wine.
Strang	Near Neider Breisig	Ditto.
Elzenburger	"	Ditto.
Alzenburger	"	Ditto.
Lutz	Near Treiss	Ditto.
Maas and Huhn	Niedar Heimbach	Ditto.
Stugerboeg	Rhine	Ditto.
Engelhohe	On the Nahe	Called wine of the Nahe; secondary wines.
Neiderborg	"	Ditto.
Leinenborn	"	Ditto.
Bangert	"	Ditto.
Rosenhech	"	Ditto.
Rensberger	Tarbach	Secondary Moselle.
Wurzgarten	Tarben	Ditto.
Amfuhr	{ Burg, left bank } { of the Rhine }	Ditto.
Rothenberger	Geisenheim	Soft, delicate, prime wine.
Scharlach	Mt. Scharlachberg	Fine flavored; rich aroma.
Roth	{ Near Hochheim, } { Spire district }	Hoch of good quality.
Königsbach	"	Ditto.
Weinheim	"	Ditto.
Forst	"	Ditto.
Ungstein	"	Ditto.
Schierstein and Narden	Wishaden	Tolerable wines.
Epstein	Near Frankfort	Middling wines.
Phillipsech	"	Ditto.
Reichenberger and Wildenstein	Erbach	Inferior Rhine wine in quality.
Fënerbach and Laufen	{ Near Fribourg, } { at Badenweiler }	These are considered the best wines of Baden.
Heidelberger and Kleingenberger ..	Baden	Good wines of the country.
Richenau Island	Lake of Constance	Ditto.

SECOND AND THIRD CLASSES.—GERMAN.—(Continued.)

RHINE AND MOSELLE.

Wines.	Place.	Character.
Meresberg and Überlingen.....	Near the Lake	Good wines of the country.
Cretzingen.....	Baden	Ditto.
Berghausen and Stellingen	"	Ditto.
Beringfield and Zeil.....	Bavaria	} Inferior wine.
Lindau and Ravensburg.....	"	
Schweinfurt.....	"	} Excellent wine, Rhenish character.
Liest.....	Württemberg	
Stein.....	"	Ditto, of a very dear price.
La Harpe.....	"	Inferior, but often sold for Stein.
Escherndorf and Schalsberg.....	"	Inferior to Stein.
Bischofsheim.....	{ Near Hanau, } Frankfort	A tolerable wine, resembling Rhenish.
Calmus.....	{ Trieffenstein, } near	} A <i>vin de liqueur</i> .
Guben.....	Aschaffenburg }	
Meissen.....	Saxony	Very poor wines.
Franconia.....	Franconia	A <i>vin de paille</i> ; aromatic.

ITALIAN AND SICILIAN.

Wines.	Place.	Character.
Lacryma Christi	Naples, Mt. Vesuvius	Red rich muscadine, of a fine flavor and perfume.
Syracuse	Sicily	Luscious red muscadine.
Reggio	Naples	Resembling Burgundy.
Baia	"	Ordinary wine.
Mascoli	Sicily, Mt. Etna	{ The best red wines in the island, of excellent body, like the secondary Rhone growths; rare in the island.
Mascoli Sciarra		
Mascoli Macchia		
Mascoli San Giovanni		
Catania	"	Pitchy taste, ordinary <i>wines</i> .
Tormina and Faro	"	Tolerably good.
Ovièto	Roman States	Excellent durable red wines.
Asti	Piedmont	Ditto.
Bianillo and Aleatico	Elba	Good wine of the second class.
Bischillato	"	A durable wine, exports well.
Procanico	"	A <i>mousseux</i> wine.
Chianti	Tuscany	A good wine.
Aleatico	"	{ Resembling the Tinto of Alicante in flavor and bouquet.
Carmignano, Antella, Artimino, } Tizzana, Mentali, Lamporecchio, } Monte Spertoli, Poncina, Glogoli }	"	Good wines of the country.
Val di Marini	"	Ditto.
Naples muscadine	{ Mt. Vesuvius } Lake Averno } Maria de Capona }	A delicate fine colored wine.
Vino Greco	"	An excellent muscadine.
Carigliano	Naples	Muscadine, flavor of fennel.
Bari and Tarento	"	Muscadine and common.
Reggio	"	<i>Vin de liqueur</i> .
Baia	"	Good ordinary wine.
Gierace	Near Reggio	Between light French wine and <i>vin cuit</i> .
Asprino	Campagna	A <i>vin de mousseux</i> .
Fundi	Kingdom of Naples	Good ordinary wine.
Val di Mazara { Mazara } Veterano } Corigliani } Termini } Girgenti }	Sicily	Of tolerable quality.
Messina, Milazzo, Avola, Vittoria ..	"	Ditto.
Lipari and Stromboli	Lipari Isles	Ordinary wines, and superior muscadine.
Imola	Near Bologna	<i>Vin cuit</i> and <i>mousseux</i> .
Terni	Near Spoleto	Good wines.
Farnese	Near Castri	Good muscadine.
Ovièto (white)	Roman States	Muscadine, not durable.
Monte Fiascone	{ Near the Lago } Bolsena }	{ A strong muscadine, finely perfumed and flavored; of great strength.
Albano	Roman States	Ditto, excellent.
Moscatoello	"	{ <i>Vins de liqueur</i> , of greater or less merit; not bearing exportation.
Aleatico		
Vino Santo		
Vernaccia		
Riccia	"	Good wine, but a small quantity made.
Buti	Plain of Pisa	Weak wine.
Monte Pulciano	Tuscany	The most esteemed of the Tuscan muscadines.
Montalcino, Rimeneze, Pont-Ecole } and Santo Stephano }	"	Good muscadines.
Vermut	Elba	A cordial wine, prepared with wormwood, &c.
Rio	"	Good muscadine.
Vino Morto	The Veronese	Deficient in spirit and strength.
Vino Santo	"	Good red and white wines.
Bellagio	Lake of Como	Wines of color and spirit.
Labusca	Mantua	An agreeable wine.
Pavia	Pavia	Both dry and <i>mousseux</i> , but very inferior wines.
Monte di Brianza	Milan	Good flavored wines.
Panocchia, Vigalto, Traversetolo, } Casola, Avola, Azano }	Parma	Ordinary wines of the country.
Val Irdone, Bottola, Ponté d'Al- lolio, Verdetto, Sala del Christo } Creta }	Placentia	Ditto.
Santo Pretasso, Frescale, Caselle, } Lassurascio, Rugarlo, Castellina, } Salso, Maggiore, Villa-Chiara, } Claretto, Pazole }	District of Borgo Placentia	{ Inferior wines, some of them <i>vins de liqueur</i> , having a disagreeable taste of honey.
Ratrera and Sapolo	Modena	Ordinary wine, for home consumption.
Vin Piccolit	Friuli	Resembling Tokay.

SECOND AND THIRD CLASSES.
HUNGARIAN, AUSTRIAN, AND SCLAVONIAN.

Wines.	Place	Character.
Tokay, Essence, and Ausbruch....	{ Near Mt. Tokay, Hungary }	See wines of first class.
Tokay, Maslas.....	"	A secondary Tokay.
Gyängyäsch.....	{ Mount Matra, Upper Hungary }	Wines, both red and white, much esteemed.
Ödenbourg.....	Lower Hungary	Ditto.
Meneser.....	District of Arad	Red, much esteemed for spirit and sweetness.
Meneser-Ausbruch.....	"	{ Like Tokay, preferred by some; rich, aromatic, sweet, not cloying.
Erlon.....	Upper Hungary	Good red and white wines, and an Ausbruch.
Rusth.....	Lower Hungary	Similar to Ödenbourg.
St. Gyorgy.....	Near Presburg	{ A white wine of excellent quality, somewhat in aroma like Tokay.
Ofen.....	Near Pesth	Good wine of the country.
Carlowitz.....	{ On the Danube, in Slavonia }	Resembles Cote Rotie.
Buda.....	{ Near the ancient capital }	Like Burgundy.
Sexard.....	{ Between Buda and Esseh }	{ Resembles Languedoc, a good red wine of the country.
Gros Warden.....	{ Near Transylvania, the fortress }	Ditto.
Schiller.....	In Sirmian	Strong and sweet, of a red color.
Wermuth { Palunia.....	"	Wines prepared with spices and wormwood.
Troptwermuth.....	"	Scarcely different from Meneser.
Glodova, Menos, Gyordk, Paulis...	Menes	Excellent wine, resembling Burgundy.
Modeon.....	Near Presburg	Ditto.
Katschdorf, Grunau, Obernusdorf...	"	
Neustoad, Zschelhæ, Kosrad.....	Near Buda	
Wersitz.....	In the Bannat	{ Wines like Burgundy and Bordeaux.
Jobbagy, Etsey, Sætvesch.....	Bannat of Tameswar	Good red wine.
Weisskirchen.....	"	Ditto.
Zips, Arva, Liplow.....	Croatia	White wine.
Buokwetz.....	"	Ditto; same quality.
Vinitza, Toeplitz.....	Transylvania	Wine of the country, Ausbruch.
Birthalman.....	Sebenico, Dalmatia	A wine highly characterized; not the <i>liqueur</i> .
Marachina.....	Moldavia	Green in color, and strong as brandy.
Cotnar.....	Wallachia	Light, rivalling Tokay.
Piatra.....	Ragusa	Good country wine.
Gravosa.....	Slavonia	Good red wine.
Semlin.....	"	{ Both red, and of agreeable flavor, and much spirit.
Syrmia and Posega.....	"	Red wines, which will not keep.
Podskalchi.....	{ Circle of Lentmeritz, Bohemia }	Ditto, like Burgundy.
Melnick.....	Circle of Bunzlow	Good wines, equal to Hungarian.
Poleschowitz.....	Moravia	Ordinary wine.
Mount Calenberg.....	Austria	
Hoefflein, Kloster Newbourg, Unter Kutzendorf, Kaplenburg, Misdorf, Salnendorf, and Lichtenstein.....	"	{ Wines of little note, generally of a green hue, and drank young.
Giberwein.....	{ Southerly, near Vienna }	{ A wine that will keep, though of no extraordinary quality.
Spitz.....	"	Good wine.
Luttenberg.....	Lower Styria	Good wines, red and white.
Radskersbourg, Arnfels, Windisch, Gonowitz, Kerchenberg.....	"	Of the next rank to the foregoing.
Sansal, Leitschach, Pickerne, Stadlberg, Pulsgau, Sauritsch, Raen, Rast, Peittersberg, Wiesel.....	"	Good wines of the country.
Moettling, Weinitz.....	Carinthia	Resembling good Italian wines.
Freyenthurn, Wipach, Tsche.....	"	Ditto.
Proseco Antignana, St. Serf Trieste	Istria	Red and white, sparkling and well flavored.
Berchetz.....	An Adriatic island	Red wine, deep colored and sweet.
St. Patronio, Petit Tokai, St. Thomas, &c.....	{ At Capod'Istria, Pirano, and Cittanova }	Good <i>vins de liqueur</i> .
Corregliano.....	Istria	A good wine, consumed at Venice.
Izeszgard.....	In the Tolna district	A superior red wine.

SECOND AND THIRD CLASSES.—SPANISH.

Wines.	Place.	Character.
Val de Peñas	New Castile	Good body, deeper than Bordeaux in color.
Manzanares	Manzanares	An inferior Val de Peñas.
Ciudad Real	New Castile	A tolerable red wine.
Albacete	"	Ditto.
Vino Tinto, Alicant	Valentia	Yellowish red color, when old called Fondellol.
Mataro	Catalonia	Good bodied and generous.
Torre, Beni Carlos, Santo Domingo, } Segorbe, Perales, Vineroz..... }	Valentia	{ Wines of good body, some of the most esteemed red growths of the country; color deep.
Hospital	Arragon	{ Excellent flavor and body, from the Garnacho grape.
Carignena	"	A vino tinto from the same fruit.
Tinto Olivencia	Estremadura	Excellent red wine, the best in Spain.
Tinto di Rota, or Tintilla	Andalusia	A sweet reddish cordial wine.
Ribidavia	Gallicia	An ordinary red wine.
Chacoli	Biscay	A very harsh austere wine.
Guindre	Malaga	Dark, flavored with cherries.
Tinto di Malaga	"	Seldom exported, a good wine.
Aleyor	{ Minorca, near } Mount Taurus }	A red wine, consumed on the island.
Palma	Majorca	A full-bodied wine.
Cordova	Andalusia	
Mirando de Ebro	Old Castile	{ Good red wines of the country.
Carbezon	Valladolid	
Terra del Campo	Old Castile	
Velez Malaga	Malaga	A luscious sweet wine.
Malaga	"	A luscious sweet wine, with a burnt taste.
Pedro Ximenes	"	A luscious sweet wine, fine and delicate.
Malaga Xeres	"	Resembling sherry, dry.
Xeres vino seco, pale and brown....	Xeres de la Frontera	Pale and brown sherry.
Abocado	"	A second growth sherry.
Huesca	"	A yellowish-white wine.
Paxarete	{ Frontera and } St. Lucar }	A sweet wine, of light amber color.
Moguer	Niebla, Andalusia	{ Used to lower the sherries at Xeres, of which it is an inferior species.
Negro Rancio	Rota	A sweet wine, of a yellow color.
Montilla	Cordova	A dry wine, of good bouquet and flavor.
Borja	{ Arragon and } Tarragona }	A luscious wine.
San Lucar di Barameda	Andalusia	A light red muscadine.
Manzanilla	"	Dry white, of inferior quality; a <i>vin du pays</i> .
Zalonge and Carlon	"	Ditto.
Yepes	New Castile	A well-flavored wine.
Fuenceral	"	A <i>vin de liqueur</i> .
Sitges and the Priory	Catalonia	Malmseys of two qualities.
Peralta and Tudela	Navarre	{ White dessert wines. Peralta is a Rancio when aged.
Pollentia	Majorca	A <i>vin de liqueur</i> .
Alba Flora	Minorca	A dry kind of Rhenish.
Vidonia	The Canaries	A wine resembling Madeira, of inferior quality.
Verdona	"	A green wine, not now made.
Palma	"	A rich Malmsey, having a taste of the pine apple.

MADEIRA AND THE AZORES.

Wines.	Place.	Character.
Malvasia, or Malmsey	Madeira	Rich and sweet.
Madeira	"	A durable, dry wine.
Sercial	"	Ditto, of excellent quality.
Muscatel	"	Not exported; a good wine.
Tinto	"	{ A red wine, changing in twenty years to rich old Madeira in color.
Figaa do Pereiro	"	{ Of inferior kind to the above.
Santo Antonio	"	
Vino Passado	Pico, in the Azores	A species of Malmsey, of light quality; keeps ill.
Vino Seco	"	A dry wine, light, not durable.

DOMESTIC WINES.—The grape ripens too seldom in England to be applied with advantage to the making of wine. The warmth of September is not sufficient to mature the grape; though up to some time in August, and generally to the end of that month, the vine may progress favorably. There are many fruits, however,

from which very palatable household wines can be made, and from which dull wines are continually manufactured, when those more lively can be introduced from the produce of the orchards, gardens, and fields of England. The mode of making these wines is generally not well understood; if it were, the wines would be much more palatable. Yeast, resorted to for the purpose of fermentation, often imparts a nauseous after-taste to the wine, which would ferment well enough in the natural way. There is nothing unwholesome in these wines, if properly made; and to this end the wine of the grape, and its mode of management, should be clearly comprehended, that its principles may be made applicable to domestic wine manufacture. The malic acid in the wines of English fruit often causes a trifling inconvenience to the *primæ viæ*, which acid may easily be exterminated in making the wine. The wine of the grape should be the model after which all wine of the garden-growth should be fermented—general principles should be first mastered. Suppose the gooseberry be taken as the fruit, it contains centesimally:—

	Unripe.	Ripe.
Green coloring matter,.....	0.03	—
Sugar,	0.52	6.24
Gum,	1.36	0.78
Albumen,	1.07	0.87
Malic acid,	1.80	2.41
Citric acid,	0.12	0.30
Lime,	0.24	0.29
Lignin, with seeds,	8.45	8.01
Water,	86.41	81.10
	100.00	100.00

The above are all the requisites for making wine, and some that are to be dispensed with; a deficiency in tartar is often noticed, but this can be supplied artificially. The excess of malic acid, on the other hand, is injurious; but as in making white wines in the South of Spain, this acid is got rid of by sprinkling powdered gypsum over the grapes, which takes it up, the same means should be adopted when making domestic wines in England.

Sugar is the first constituent in wine-making, and as it does not abound in some garden-fruits in England, it must be added. Cane-sugar, it has been seen, differs from grape-sugar in its proportional parts, but it is converted into grape-sugar by the process of fermentation. It is a sugar which goes slower into fermentation than that of the grape, and the alcohol in the wine always bears a proportion to the pre-existent sugar. This sugar uniformly contains a portion of a vegetal extractive matter, unless it is separated from it by art. The natural sugar of some plants also contains, some more, others less, of this sweet vegetal matter. If there is much of it in the sugar, the wine will be dry and perfect, because all the sugar will have been changed into alcohol. The mucilage, or vegetal extractive matter, like the gluten of wheat or albumen, contains azote, the gas of which has been noticed in grape wine making. This matter, found too in yeast, thus acts in exciting fermentation. Most garden fruits possess it; and it is this sweet principle combined with that in sugar, which operates the conversion with other wine, as with the grape. Water is another constituent. As to

the other substances, except tartar, they rather concern the curious in chemistry than the maker of family wines, for some can only be detected by the close scrutiny of the experienced chemist. Little color can be communicated to any of our domestic wines, if the elderberry, currant, blackberry, and black cherry be excepted; but this is a matter of little moment in that which should rather be adopted to please the palate than the eye. If astringency or roughness be in request, that loss may be innocently supplied by the application of catechu. The damson and sloe alone possess it naturally.

The substances necessary to vinous fermentation, the sugar and its sweet principle, the natural vegetal extract, the tartaric acid—in place of which latter the malic acid is often found, which should be dispensed with, and tartar added artificially—and water; these in certain preparations, and in their differences, are the essentials in this class of wines. Sugar is the most important, and its decomposition gives out the alcohol, on which the strength of the wine depends; therefore its quality is of great importance. When the sweet principle and sugar—for they are in union—have disappeared in fermentation, and there is no more vegetal extractive matter belonging to the fruit in the liquid, the wine is a dry wine, and is in its perfect state. If the sugar be in excess, the result is wine and sugar; vulgarly, a sweet wine. If the vegetal extract be in excess, and the fermentation too prolonged, acetic acid will be the product.

The want of attention to the foregoing points often renders the making of dry wines a failure. No yeast should ever be used. If the vegetal extractive matter be wanting, the lees of other wine may be tried; but this is seldom needful, with due care. During fermentation the leaven or ferment is insoluble, and rises to the surface, or falls to the bottom. On restoring this to the surface, the fermentation may be prolonged at pleasure, until the necessary dryness be gained. To attain a sweet wine, the fermentation should be stayed by separating the wine from the ferment, and fining it with isinglass or white of egg. Thus the ferment is separated, and the operation suspended; it may be renewed by restoring the separated matter; if not, a sweet wine remains. It cannot run into acetous fermentation if its leaven be expended; but still there is hazard, and some care necessary, in thus renewing the operation.

Of these acids, sometimes found in fruits—the tartaric, malic, and oxalic—only the first two have any share in the fermentation. Tartar abounds in the grape, and to that its superiority is ascribed. It is wanting in our domestic fruits, or very scantily bestowed. Malic acid is predominant in apples and pears, and they give liquors very different from wine. Crude tartar is best added to the must for domestic wines, not the purified salt.

Care should be taken not to carry on fermentation in new wooden vessels, nor to place wine in them without due preparation. The vegetal extract in the wood will infallibly set the fluid in fermentation, as is well known to the French wine-grower.

The end of the fermentation is the production of the alcohol; and the chemical action involved is well

understood, although the primary force of the ferment is not, nor can it be, so well comprehended. In this respect Nature eludes the efforts of the chemist and physiologist to define correctly her workings, or submit a true definition of the affinities which are continually set in motion by natural force. As regards fermentation, it is true that only the salient points of the chemical changes are understood, but they are sufficient to govern the industry of the fermentation of liquids of every kind, provided all that chemistry has revealed be known to the operator. In domestic wines no just rule has been regarded. Most of the directions are based upon false principles, and display extraordinary ignorance, according to Dr. McCULLOCH, who has written so well upon the subject; and if not clear to the family makers of such wines, and too scientific for the common concoctors of them, his work still is not the less worthy because the stolid do not perceive its merits.

BRANDE made analyses of the strength of some of the domestic wines, which are appended. The alcoholic strength was per cent. at eighty-nine alcohol and eleven water.

Wines.	Per cent.	Wines.	Per cent.
Grape,	18.11	Orange,	11.26
Raisin,	26.40	Elder,	8.79
Do.	25.27	Mead,	7.32
Do.	23.20	Cider,	9.87
Do. average, ..	25.12	Do.	5.21
Currant,	20.55	Do. average, ..	7.54
Gooseberry, ..	11.84	Perry, average, ..	7.26

Before going into the practical part of the subject, the warning against the use of yeast must be repeated. It is a vile substance when in contact with anything vinous, imparting a base flavor, and is to be altogether shunned. The regulation of the temperature, too, is to be sedulously regarded, that the fermentative process may not proceed too rapidly. The bulk of the must to be fermented, and its exact quality must be well considered; the addition of flavoring substances, and finally, the proper vessels adopted for the different operations.

The fruits most commonly employed for making domestic wines are the elderberry, cherry, raspberry, sloe, damson, quince, strawberry, mulberry, gooseberry, lemon, orange, and two or three kinds of currants. Of these several do not retain their flavor, and are to be rejected on that account. The flavor of the strawberry is not communicated to the wine, nor of the quince or raspberry. These might be infused to advantage nearly at the close of the fermentation of some tasteless must, and thus their flavor be sustained in the wine. The blackberry and mulberry should, as in the instance of grape-wine, be allowed to go into fermentation, skins and all, for the sake of the color. The damson and sloe make a good rough wine, but care must be taken to proportion the sugar to the fruit as to quantity, and by protracting the fermentation, to make a dry wine. By a due admixture of elderberries or currants with sloes and damsons, wines like inferior ports are often easily produced. The proportions vary according to the season. The elderberry may be made to yield an excellent red wine. It possesses enough of the extractive principle to impart a very rich tint, and even a

fine deep color. Tartar should be introduced into the must; and, besides, this berry requires much sugar, as the saccharine principle is scanty.

The gooseberry is known as giving a species of champagne to the list of domestic wines, which are made to effervesce; but, in order to answer, the gooseberries are used in an unripe state. The effervescing property always results from the use of unripe fruit, and will be readily produced by mixing ripe and unripe grapes together; and it is the same with the gooseberry. In general the flavor is bad, and to avoid it, as it is imparted by the ripe fruit, the more unripe should be prepared. This wine should be made with the expressed juice of the fruit alone, and nothing else should be fermented, the skins not being suffered in the must. By this means any disagreeable or peculiar taste is avoided, and the wine, if nearly tasteless, is brisk, pleasant, and perfectly free from any bad flavor. To make this wine, three pounds of sugar, and four of fruit, are allowed to eight pounds of water. Five pounds of fruit would be better, to avoid sweetness, though in complete fermentation; the wine would then be amply strong. No brandy should be added to effervescing wines. Care should be taken in bottling, and the same attention bestowed upon genuine champagne should be bestowed on this imitation wine, which will readily repay the extra trouble. This wine arrives at perfection only in the cellar. Wine made from ripe gooseberries is good for little; but if attempted, the skins must be carefully excluded.

In such wines too little fruit in proportion is used. In currant wines the fruit is always stinted, there being sufficient extractive matter and natural acid to insure, if rightly arranged, a very perfect fermentation. These wines are made too sweet, and pall upon the palate. The proportion adopted is in all cases to be increased as regards the fruit, and the skins to be excluded from the must. The recipes, so manifold, handed about for domestic wines, continually show that the true principles of making such wines are not recognized, although laid down so lucidly by Dr. McCULLOCH. British champagne is directed to be made by crushing the fruit with a mallet, and a gallon of fruit is to be put to a gallon of water; then brandy is added, and sugar of the species often to be avoided; and brandy is added again in bottling. McCULLOCH recommends boiling the fruit, in some cases, previous to fermentation. The black currant acquires, by boiling, an agreeable flavor. The success of the plan is remarkable; the more so as, in its natural state and unboiled, it is harsh. The wine made from it much resembles sweet Cape wine. The same improvement takes place in regard to the red and white currant. The boiling should not be protracted. It is always best to boil about a third of the quantity used, and to apply the rest in the natural state. The boiling must not be continued too long, because it tends to precipitate the ferment.

The dried raisin is largely used in making domestic wines; and it naturally must be analogous in some respect to certain foreign wines, because for making them the grapes are not used until they are shrivelled in the sun. Thick, sweet grape-wines are made this way. The process adopted in making raisin-wine in

England has not shown any approach, with the same materials, to the wines made of dry raisins, or such as are called *straw wines*, or some of those of Malaga. In the mode actually adopted here, whether for domestic use, or for the deceptive objects of wine-dealers to mingle with foreign wines, from two to seven pounds of raisins are employed to a gallon of water, common clayed sugar or molasses from half a pound to three or four pounds, and oftentimes from four to six pounds of tartar in the crude state are added. Yeast is not used; still the wine is never well-tasted, and to obviate that, as the bad taste may arise from the skins, cold water is used. It is necessary to apportion the sugar to the tartar. From two to four per cent. of crude tartar is a sufficient addition, giving more when the fruit is sweetest. In regard to the sugar, two pounds to the gallon of the other ingredients will produce a light wine like the white wine of Bordeaux. Three pounds will give the body of hermitage, and four that of Muscat or of Cape Madeira, before their respective doses of brandy were added to them. The sugar added must be apportioned to the quantity in the fruit. If the wine is to be a sweet wine, not less than four pounds to the gallon must be used. The water added must not be out of all proportion to the fruit—which last rarely forms a fourth of the entire fluid—and four pounds to eight of water, and three or four of sugar, supposing no regard is had to the state of the fruit in respect to its ripeness. The vegetal extractive matter in such a case is deficient, as well as the native acid, and this acts injuriously upon the fermentation, and renders it inefficient; the must, consisting of an overplus of sugar and water, cannot thus form wine. Let the principle wanted be increased, and the wine will put on the true character—the dilution of the acid, if the fruit be ripe; and if it be unripe, then the acid and extract being in excess, the operation must fail of fulfilling expectation.

Flavor may be easily imparted to all those wines which want it. Elderflowers, mignonette, clove pinks, for example—or sweet briar, wormwood, ginger, cloves, orris, and the like—will impart, either of them, or perhaps some in combination, a flavor agreeable to the taste of the maker. They are suspended in a bag from the bung-hole during the first stage of fermentation. To please the eye, elderberries, or mulberries, will supply color, or what the French call *vin de fismes*—a color liquor, made near Rheims of a small bitter cherry used for the same purpose, a few drops being sufficient to color a bottle. In Holland, tounsel is used for the same purpose—the *crotum tinctorium* of Linnaeus. It is naturally of a blue color, but on coming into contact with an acid it immediately takes a red hue. In France it is said that color derived from woods, as Brazil or logwood, do not long resist the acid of the wines; and, therefore, they find it better to darken the light hue of wines by mingling deep-colored wine with them. This, however, need not deter from the use of such means to suit the eye in domestic wines of English fruit. Bitterness may be obtained by the use of burnt sugar, as well as yellow tints. Cognac brandy for the English market is thus colored in France, where the people use the pale spirit.

All vinous operations require great care and sound

VOL. II.

judgment. In fining home-made wines, the same management is necessary as in treating the grape-juice with a similar object. The imitation wines made in the household must first be considered in regard to the model immediately in view. If the object be a sweet wine, of which the fermentation is incomplete from the want of sugar in the must, or if its suspension be by design as before described, the operation to be followed is clear.

If the wine be designed to sparkle or effervesce, the cause and mode of acting has been shown; and that briskness is not much in accordance with sweetness. Though generally made of the gooseberry, any other fruit in a proper state of immaturity will answer as well. The use of carbonate of potassa or soda must be avoided, because the gas is almost all disengaged in the first glass on pouring out, before the wine can be drunk, nor has it anything like the effect of carbonic acid gas in the wine. It also deteriorates the taste, and destroys the native acid, replacing it with an alkali.

The Rhenish wines have never been successfully imitated, and for the paramount reason, that their constituent parts are so accurately balanced that they would require great judgment, and much care, in the process; the fermentation must be perfect, and exact proportions be carefully kept in the ingredients. Even then their preservation would require great attention. Fining, racking, and sulphuring, must be had recourse to by hands often not adepts in their use. The dry wines of some strength, imitative of Sherry and Madeira, may be made strong enough without the addition of brandy, which, however, may be added to them by the operator, if he sees it requisite.

Dr. M'CULLOCH recommended that wine should be made from grapes grown in England. The grapes may not ripen in some years, and in an agricultural view it is profitless; but wine is continually made by cottagers in Sussex from the grapes grown in front of their houses, and some species ripen a full month before others. The white muscadine, the two varieties of the chasselas, the black Hamburg, and others, are of this class. But to make domestic wine from the grape in England, does not demand that the grape should reach the maturity required for its wines, as the term is generally understood. A crop of grapes is certain, if not always a ripe crop. A compound artificial must can be made from the admixture of sugar with the extractive and other matter of the fruit, which, undergoing a regular fermentation, forms a perfect wine, as applicable to the grape as the gooseberry. The experiment has been tried and found successful, and domestic wines made this way declared excellent. Three pounds, or less, of sugar to the gallon, with the hardest grapes, produce a wine of the strength of red hermitage, not void of flavor, but the reverse. Dr. M'CULLOCH mentions the proportions he found needful, both of sugar, water, and other substances necessary for the purpose. He kept some of the wines twenty years, and found them as little liable to destruction as the wines of France.

The want of judgment, the haste, the non-comprehension of the chemical principles upon which wine is made from domestic fruits, the want sometimes of a clean palate on the part of the maker, and the aban-

donment of a nice operation to the hands of servants and old housewives, have caused great mistakes in the manipulation of these wines. Dry wines of the first quality do not require that maturity of the grape which is so necessary to those which are sweet. In the first case sugar can be added; but the customary notion of the ignorant in this, as in other cases, often prevails, and the neglect of the green grape for the green gooseberry is a striking proof of it. Nor is this all; for it has been proved by chemical examination, that the tendrils, shoots, and even the leaves of the vine themselves, possess exactly the same qualities as the crude fruit. Experiments were in consequence instituted in France, to try if they would not answer for the purpose, and they were satisfactory; but there, where the fruit was to be had in any state, the matter naturally terminated; while in England it was different. The success of the attempt was decisive, on adopting the management had recourse to in treating wine from other unripe fruit. Only young or half-green vine leaves are selected, together with the tendrils. The old leaves are not proper. The month of June is the right season to pluck them. The vines for the purpose may be planted anywhere, and suffered to run up unpruned. Close imitations of the sparkling wines of Champagne and of St. Peray have been made this way, and none were made that were not as good as the ordinary sweet wines of the Cape. If the wine is too sweet from want of the vegetable extract in a sufficient quantity, a fresh infusion will reinstate the fermentation. The wine of a defective year in goodness, may be renewed the next season. The leaves should be infused sometime before they are used, yielding their virtues more readily to hot than cold water without any material difference in the result. Half a pound of crude tartar, or more, within a pound, to two gallons of must, is useful. The expense of the sugar here is nearly the whole incurred, and a single vine will supply a family, as the leaves are successive.

A few specific directions under the scientific authority before mentioned:—The cask measure being supposed ten gallons, will illustrate the foregoing principles; those adapted to the lands of the vine being kept in view as guides, where any difficulty may occur. In a tub or vat carefully cleaned, that has a capacity for fifteen or twenty gallons, forty pounds of the gooseberry of the green Bath kind are introduced, avoiding any that are ripe. Reject the unsound, and remove the blossom and fruit-stalk, or their remains. The small berries may be separated by a sieve. The fruit is to be bruised into the vat by a pressure sufficient to break the skins, without fracturing the seeds or compressing it too much. Four gallons of water are then poured in upon the fruit, and the whole is carefully stirred and compressed with the hand, until the juice and pulp are separated from the solid matter. The materials must rest for ten or twenty-four hours, and then be strained through a coarse bag with as much force as can be easily applied. A gallon of fresh water is to be added to the mash, to remove any soluble matter remaining. From twenty-five to thirty pounds of white sugar are to be dissolved in the must

or juice thus obtained, and the mass of fluid increased by more water to ten gallons and a-half. This difference in the weight of the sugar is to balance any in the quality of the fruit, the discovery of which difference must depend upon the judgment of the operator. Old haphazard receipts gave forty pounds of sugar, which of course make a sweet wine, continually failing in effervescence on that account. The must is next to be placed in a tub or vat, over which a blanket is thrown, and a board over that, and the whole kept in a temperature between 55° and 60°, to remain from twelve to twenty-four hours, according to the state of the fermentative process. It is then to be drawn off into a cask until the fluid nearly reaches the bung-hole, so that the scum which ascends to the surface may overflow, and be thrown out. As the fermentation goes on, and the bulk of the liquid diminishes in the cask, the superfluous must made for that purpose must be poured in, so as to keep the liquid always near the bung-hole. When the fermentation diminishes still more, which may be judged of by the reduction of the hissing sound, the bung is driven in, and a hole bored on one side of it, into which a wooden peg is put, and in a day or two taken out, in order that the gas within may have vent. It is then restored and reopened to let the gas again escape, until, there being no longer any danger from the expansion, it is tightened for good. The wine is to be kept over the next winter season, in a cool cellar, and on a clear sharp day about the beginning of March, if fine, it is bottled; if not fine, or to insure its fineness, if doubted, at the end of December it is decanted into a fresh clean cask, to free it from the lees, which, if the wine be too sweet, instead of drawing it off, should then be stirred up in it, increasing the temperature to renew the fermentation. When drawn off, it is fined with isinglass; and if not clear, the operation is repeated in dry, clear, cold weather as before, and bottled in March, and not later. Such a wine is brisk like champagne, and similar in quality, but stronger, differing in little but the flavor. Sometimes the wine will be still, like sillery, or sweet, without close attention to the process; at other times it will be dry. If sweet and still, it may be remanufactured the next season by renewing the fermentation, and repeating, under the addition of fresh juice or must, the former treatment. If it be dry, it remains so, and may be drawn off into a sulphured cask, and then fined and bottled. Any peculiar and not agreeable taste, during the first year, will go off by age. Such wines are best when drunk at five or six years old. In making the foregoing wine, the mode in managing grape-wine—fermenting the husks or skins as well as the juice with the sugar—may, on the other hand, be adopted in the earlier stage of the operation. The rapidity of the fermentation in this way is much increased; the wine, stronger and less sweet, will gain more flavor. Crude tartar, to the extent of six ounces to the ten gallons, is sometimes added. Sweetness with briskness, though the latter quality is hazarded, may be had by using sugar to a greater extent under forty pounds. Brisk domestic wines are not durable nor strong, and must be drank very early from want of the capacity for keeping. Effervescence without sweetness

is obtained by increasing the fruit, as in the proportion of fifty pounds of fruit to thirty of sugar.

The wine made from unripe currants, under the same general process as the former, requires that the stalks be separated with care. The must of this fruit is much easier to manage than that of the gooseberry, and it is far better calculated for brisk wine, and less likely to carry a bad flavor.

Nothing but the pure must is introduced into the cask—not a particle of the mash. If, in the fermenting in the vat, the scum, crest, or head, called the *chapeau* by the French, be tainted with sourness or mustiness, it must be at once removed; and when the fermentation of the mash does not take place with the must, the latter may be at once introduced into the cask.

Mature gooseberries and currants are made to produce dry and sweet wines by the foregoing modes. In sweet wines the fruit should not be above forty pounds; if in dry, it should be carried to sixty. The sugar should be full thirty pounds, unless a strong wine is desired, when forty pounds must be employed.

Wines from elderberries are made with the same proportions of ingredients as the former kinds, and in the same manner. If boiled fruit is taken—an operation which relates almost wholly to the black currant—the fruit must only be brought to the boiling point of the water, and the burning of it at the bottom of the vessel must be guarded against. Wine from the mature grape in this country it is not worth while to manufacture, as too few grapes ripen to make it any other than an object of curiosity, and the mode of treatment of them, described in the preceding pages, contains all that is necessary upon the subject.

It is probably due to M'CULLOCH that it was ever known that domestic wines could be made from immature grapes, vine tendrils, the young leaves, and the thinnings of the branches in places where vines are grown under shelter, in different stages towards maturity, no matter how different in species. No part of the vine need be feared as communicating a bad flavor. If the immature grapes be those grown in the open air, they should be taken just at their first tendency to ripen. The proportions and treatment are similar to those recommended for the gooseberry, but the husks may always be fermented in the vat with the must. Except in not breaking the seeds, no care need be taken about not bruising the fruit. The fermentation will be slow; but no obnoxious yeast is to be employed. Patience is necessary, but the operation will not ultimately be less effectual. Elevation of the temperature will excite it, if languid; as will also agitation of the cask, or omitting to replenish the fluid at the bung, so that the scum may remain upon the liquor.

The wine made from the young leaves, tendrils, and even young shoots, may be taken at any period from vines cultivated for this object, from which fruit is not expected. If the claret vine—*Clairrette rouge de l'Herault*—be cultivated for the purpose, the wine will be of a red color. The leaves should be young, and sixty or eighty pounds should be introduced into a vat. In the vicinity of a large town they should be first washed, to clear them of sooty particles from the impure atmosphere. Seven or eight gallons of boiling water

should then be poured upon them, and left to infuse for twenty-four hours. The water being poured off, the leaves are pressed in a press of considerable power, washed with an additional gallon of water, and again pressed. Sugar, from twenty-five to thirty pounds, is then to be added to the mixed liquors, and the whole made up to ten gallons and a half, when the same process is to be pursued as in the case of gooseberry wine. The water soon cools down to the usual temperature, it being used hot in order more effectually to extract the soluble part of the plant or fruit. These proportions are for brisk wines, which, if mismanaged, will fail of due effect. In the case of sweet wines of the same substances, from thirty-five to forty pounds of sugar must be used. As soon as the first fermentation has subsided, the wine is racked into a sulphured cask and fined. If it tend to a renewal of the fermentation, it must be racked and fined again, and even a third time. When perfected, the wine may remain in the cask as long as is desired. For dry wines the proportion of fruit to the sugar is to be the largest of all. The bung must be left open, and the fermentation, if sluggish, must be increased by heat and agitation. If the wine continues too sweet, it may be bunged down until the next spring without fining, and then the fermentation must be renewed by adding fresh must. As soon as it has become sufficiently dry, it must be fined into a sulphured cask, and again fined before bottling. The dry and sweet wines of this kind should be kept five years to be in their highest perfection. The brisk wines are drank after being six months in bottle, and are good to their third year. If they lose their briskness, they become dry, something like the Moselle or Rhine, and will keep indefinitely.

Wines, if they can be so called, are also made of dried substances, as ginger. They are composed of sugar and water, fermented with yeast and flavored with ginger. These are rather drinks than wine. The last are made by fermenting substances which possess little or none of their own extractive vegetal matter. Three pounds of moist sugar, a gallon of water to two ounces of bruised ginger are boiled, skimmed, and set to ferment with a yeast toast, flavored with a lemon to each gallon, or a little balm, and then bunged up. In about two months it is fit for drinking, having been fined with isinglass.

Mead, a very ancient domestic wine of honey, is made with sixty gallons of pure soft water, and seven gallons and a half of clarified honey, of which mellitose—see SUGAR, Vol. II. p. 966—is the sweet principle. In a copper of thirty gallons capacity, having mixed the honey and water, boil it down to one-fourth, then let it off, and boil the other moiety in the same manner; and when thus reduced fill up the copper with what was boiled first, and continue ebullition and filling up until the copper will contain half the liquor, all the rest having evaporated. The liquor must not be skimmed, but the scum must be well mingled with the liquor while seething, by means of a jet. When this is done it is drawn off into under-backs by a tap in the copper, and the fluid falls to the temperature of new milk. Then it is turned up and fermented in the vessel, where it forms a thick head. When it has

ceased to ferment it is closed from the air, and bottled at the end of six months, having been well worked and kept in the same cellar temperature as it had before. Aromatic flavors are often added by mixing elder or rosemary, marjoram flowers, and the like; or cinnamon, cloves, or other spices, during the process.

Raisin wine was manufactured light and dry in England of a superior kind, by Mr. AIKIN, secretary to the Society of Arts in 1829. Dr. M'CULLOCH censured the mode in which it is generally attempted to be made, and noticed the failure which is naturally to be expected from the use of molasses, coarse sugar, and the nauseous yeast of beer, which can never be rendered vinous. He would have the native acid neutralized, and with all domestic wines use crude tartar. Mr. AIKIN's wine was produced from Muscatel raisins. These, it is obvious, being sweet and dry, were not very different from some of the shrivelled and dried-up grapes with which wines are made in the South of Europe, as in the example of straw wines, for which the grapes are kept on the vine till shrivelled, and then further dried upon straw, giving a thick must, scanty in proportion to the produce, in a state of the grape so over-mature. Muscatel raisins are imported in boxes of twenty pounds weight. The fruit kept in the warehouse or shop unsold for above a year, is less approved by purchasers than when new, the rich pulp becoming mixed with the saccharine concretions. The extractive matter or gluten in the raisin is more than sufficient to ferment its sugar, and only from one-tenth to a third of the weight of the raisins is added. Cane sugar should be avoided in the unrefined state; if used it should be loaf. Sugar from honey or starch would be best, as unrefined sugar of the cane taints the wine. The raisins, without the stems, are chopped fine on a board, in the mode adopted with minced meat. Three pounds of raisins and one pound of sugar, were used to an ale gallon of water. The next process is mashing or maceration. If the former mode is adopted, the chopped raisins are placed in a tub, and hot water, a quart to four pounds of fruit, poured over them—the water not heated above 120°—to extract the mucilage. The whole is then stirred with the hand, no lumps being left, and placed in a sieve over a tub a short time to drain; this operation is repeated a second time throughout. The clamminess of the mass is by this extracted. The water for a third mash is poured on at 160°. The liquor now begins to be acidulous, with little sweetness. Three-fourths of the mash being made and tasted, to discover if it be sufficiently astringent, the stems or stalks, in part or all, are used, according as more or less astringency is intended. Hot water is poured upon the must, and the whole is well pressed by the hand. The three first mashes are now thrown into the tun, and the sugar, with as much of the last mash as will bring the must to its due proportion of one ale gallon to three pounds of fruit and one of sugar. The operation so far requires four or five hours; the temperature of the must is about 70°. The liquor soon ferments according to the atmospheric temperature and its treatment, but generally within thirty-six hours. The scum is either duly removed, or suffered to remain till the wine is drawn off. If the fermentation is languid, the cover is kept on the tun

and the scum stirred into the liquor; if too rapid, the cover is taken off and the scum removed as it rises. The must is thus become vinous, and is transferred to carboys, or stone-ware barrels, holding six or seven gallons. Safety tubes of glass are placed in the bungs, and on the second day an inch of quicksilver in the tube, to exclude the air. The bungs are covered with a cement consisting of wax and rosin. Carbonic gas bubbles through the quicksilver for some weeks, when it ceases. The wine should remain for the summer in the carboys, or barrels, if the latter be used. The wine thus made in April should be bottled in March, or if made in October, be bottled in September. The wine is not fined, for a light dry wine the inventor thought would be injured by being deprived of its tannin. After a year in bottle the wine had a bouquet like elderflower. As the wine is not fined it is decanted with care to keep it clear. It is of a pale yellow color, but in a short time deepens to the tint of Bucellas, having a flavor something like prussic acid at uncorking, which disappears. If, in place of mashing, maceration is applied, putting the chopped raisins and sugar into cold water, a higher colored wine is obtained, the fermentation is slower, and it is destitute of the elderflower bouquet, acquiring a taste from the husks of the raisins; but often this second mode of treatment answers well. It is sometimes twenty days under fermentation. Tartar is often added in making this kind of wine, but it often fails to be good—generally from the use of molasses, cane-sugar, and yeast.

Makers of domestic wines, it must be repeated, fail from not, before commencing their attempts, becoming perfectly acquainted with the mode of making foreign grape-wine, and the principles upon which it is done, which are applicable to all domestic wines, almost without exception. They are scarcely ever what they are capable of being made. In the evidence on the wine duties, before a Committee of the House of Commons, Mr. A. WALKER and Mr. J. FRITH were examined. They deal in wine, home-made, of all kinds, and some bearing foreign names. The wholesale price by the hogshead was five shillings per gallon. They make sixty-five thousand gallons, of which ten thousand are British port and sherry. It is estimated that six hundred thousand gallons of these wines are made. Port is imitated from the black cherry; champagne from French grapes; port, partly too with French grapes and raisins; and Cape or Pontac, with bottoms of Oporto and Spanish wines. Spirit is added to them all. Some champagne, home-made, is from rhubarb and gooseberry. It is averred that any light wine may be made to pass for home-made champagne, by means of sirup and carbonic gas, applied as if to aerated waters. However this may be in practice, Dr. M'CULLOCH so well explained the process of making these wines, that success is sure wherever the guide he has left is followed; and if the domestic manufacturer be not successful, it is not for want of the soundness of the principle, but of the practical action arising from its knowledge.

WINE MEASURES.—The imperial gallon wine measure which superseded the old contains ten lbs. avoirdupois of distilled water, or 277·274 cubic inches. The old wine gallon was equal to two hundred and thirty-one

cubic inches, the ratio being nearly as six to five, or more correctly as one to 0·833111. The imperial

wine-pint is 34·65925. The old English wine measures were:—

Tun.	Pipes.	Puncheons.	Hogsheads.	Tierces.	Barrels.	Rundlets.	Gallons.	Quarts.	Pints.	Quarterns.	Cubic Inches.
1	2	3	4	6	8	14	252	1008	2016	8064	58212·
	1	1½	2	3	4	7½	126	504	1008	4032	29106·
		1	1½	2	2½	5½	84	336	672	2688	19404·
			1	1½	2	3½	63	252	504	2016	14553·
				1	1½	2½	42	168	336	1344	9702·
					1	1½	31½	126	252	1008	7276·5
						1	18	72	144	576	4158·
							1	4	8	32	231·
								1	2	8	57·75
									1	4	28·875
										1	7·219

Wine measures differ greatly in the European wine-making countries, and give much perplexity in conducting operations of any kind in regard to them. Thus a tun is two pipes; three puncheons, four hogsheads; six tierces, two hundred and fifty-two old English gallons; and one thousand and eight quarts, two thousand and sixteen pints. The following are some of the more common measures:—

	Old Gallons.	New Gallons.
Tun,.....	252	210
Pipe of Port,.....	138	115
Do. Carcavellos, Lisbon, Bucellas,.....	140	117
Do. Madeira,.....	110	92
Do. Sicilian, Marsala,.....	112	93
Do. Vidonia, Teneriffe,.....	120	100
Butt Mountain, }.....	126	105
Do. Malaga, }.....		
Do. Sherry,.....	120	100
Hogshead, Claret,.....	57	46
Do. Tent,.....	63	52
Ohm Rhenish,.....	36	30
Do. Aix-la-Chapelle,.....	—	35
Do. Cologne,.....	—	41
Do. Heidelberg,.....	—	29
Do. Cassel,.....	—	43
Do. Frankfort,.....	—	39

The French measures are the litre and hectolitre. The first contains 61·0280264 cubic inches; the second, 3·531714693 feet English; or the litre is equal to 2·113 pints old English wine measure, and the hectolitre to 26·4 old English gallons, or to 22·01 gallons imperial, and the litre to 4·5432. Therefore, 100 imperial gallons are 454·3200 litres. A pipe of port contains 522·3680 litres; a butt of sherry, 490·6656; a hogshead of claret, 208·9872, and an ohm of Rhenish 136·2960. In France, let the name of the cask or measure be what it may, the stranger asking the number of litres, is at once answered—the litre being the legal standard.

FRENCH WINE MEASURES WITH OLD ENGLISH.

Litres.	Cubic Inches.	Imperial pints.	Old wine pints.	Oz. of water, troy.
1 =	61·028	1·7608	2·11353	31·104
2 =	122·056	3·5216	4·22706	64·208
3 =	183·084	5·2822	6·34059	96·312
4 =	244·112	7·0430	8·45412	128·416
5 =	305·140	8·8038	10·56765	160·520
6 =	366·168	10·5646	12·68118	192·624
7 =	427·196	12·3253	14·79471	224·728
8 =	488·224	14·0861	16·90824	256·832
9 =	549·252	15·8469	19·02177	288·936

In some countries a troublesome variety prevails in measures of the same name. In Sweden, the ohm is 139·019 litres, or 30·543 gallons imperial; at Strasburg it is only 46·093 litres, or 10·146 gallons.

The measures for wine in Spain are commonly arrobas, of which sixteen make a mayo; twenty-seven mayos, a pipe; thirty pipes, a bottle—the last equal to one hundred and twenty-seven and a half old English gallons, or one hundred and six imperial. But the measures of the same name differ in different provinces. The arroba of Valencia contains 11·786 litres; of Malaga, 15·850; of Spain and the Canaries generally, 16·073. The cantaro of Alicante is 11·554 litres, or about three gallons, and the tonelada is one hundred cantaros; that of Arragon, 10·313; of Oviedo, 19·236. The carga of Barcelona is 123·756; the gerra of Minorca, 12·063; the mayo of Galicia, 161·991; the quartin of Majorca, 27·131 litres, or 7·168 old gallons.

In Portugal, the almude is 25·480 litres; of Lisbon, 16·541; of Oporto, twenty-one make a pipe; at Lisbon, thirty-one, or one hundred and forty old English gallons. At Figueras the almude is 4·75 English imperial gallons; at Viana, 5·5. All these are in use in Portugal; besides which, they have potes, canadas, quartillos, basils, and toneladas; this last two hundred and thirty-one imperial gallons.

In Germany the ohm varies, at Hanover and Hamburg it is thirty-two imperial gallons; on the Rhine only twenty; at Ratisbon the bergeimer—about nineteen imperial gallons, and the same at Munich—seven and a half only; at Vienna it is ten and a half imperial gallons. The ohm at Basil, in Sweden, Dantzic, and Strasburg is a different measure from the German ohm. The ohm at the Cape of Good Hope is thirty one and two-thirds; the eimer of Leipzig, twenty and a half old English gallons, and at Dresden eighteen only; at Antwerp the aum or ohm is forty-two old English gallons.

The Russian wine-measure is the vedro of 2·705 imperial gallons; three vedros make an anker; six ankers, an oxhant; two oxhants, a pipe, or 75·320 imperial gallons.

The Hungarian measures are, the antheil of 11·125 imperial gallons; the great and little eimer—the first equal to 16·140 imperial gallons, and the second to 12·515.

The other European wine measures are of little moment comparatively. In Italy they are numerous. The oke in Greece is two pounds, three ounces, five drachms, avoirdupois; and the alma of Constantinople, 1·150 imperial gallons.

Mr. CYRUS REDDING kindly tendered some valuable matter, which the Editor has incorporated in the preceding details.

ZINC.—*Zinc*, French; *Zink*, German.—It is only from the middle of the sixteenth century that zinc has been known as a metal. Its ores were known from a very early date, and were spoken of under various names; but the first account which is recorded of the term *zinc* being used in reference to the educt from the calamine or cadmia of the period, is that of ALBERTUS MAGNUS; and the first who characterized it as a distinct metal was PARACELSUS, about the year 1530. For a long time afterwards, however, the knowledge of this substance was almost entirely confined to alchemists, who prized it highly on account of the property which it was thought to possess of transmuting copper into the more precious metals. It was owing to this imaginary property that the metal was long termed *counterfey* or *counterfeht* by the Germans. The present name seems to be derived from the word *zinken* or *zacken*, the German for nails or spikes, because, in preparing brass, a portion of the ore, on being sub-

mitted to a preparatory roasting, often assumed such forms. The synonym *SPELTER*, which is now so much used in commercial language, is derived from the terms *spiauter*, *spialter*, *et cetera*—terms which were introduced along with the first portions of this metal imported from India.

That the ores of zinc were known to the ancient Greeks and Romans, is attested by the accounts which DIOSCORIDES, STRABO, and PLINY give of one of them, or perhaps of several of them under one generic name; and likewise by the fact that in the time of these writers or at a later period, articles are known to have been produced in a kind of brass or bronze, the analyses of which clearly indicate the presence of zinc in greater or less proportion. The following analyses of different varieties of brass, dating from about the beginning of the Christian era, are given by PHILLIPS as demonstrating this fact indisputably:—

		Copper.	Tin.	Iron.	Zinc.	Lead.
Large brass of the Cassia family, B.C. 20	82.26	0.35	17.31
Large brass of Nero family, A.D. 60	81.07	1.05	17.81
Titus,	" 79	83.04	0.50	15.84
Hadrian,	" 120	85.37	1.14	0.74	10.85	1.73
Faustina, jun.,	" 165	79.14	4.97	0.23	6.27	9.18

Of many other bronze articles analyzed by PHILLIPS, none of them, known to have been produced anterior to the year 20 before CHRIST, were found to contain zinc as a constituent, tin being the material employed instead of that metal. The earth which was used in those early days for the purpose of forming an alloy with copper was termed *cadmia*; but it is evident that by this substance was not meant an oxide or silicious oxide of zinc, as at the present day, but any mineral, whether oxide or carbonate, that contained a large proportion of that metal, notwithstanding there being other metallic compounds associated with it. The alloy so prepared was known as *aurichalcum*, which was then recognized as a purer copper than the ordinary metal, and hence was more esteemed. The dross or oxidized portion sublimed from or remaining in the furnace after the alloy was drawn off, was likewise known by the general term *CADMIA*, but was distinguished by some particular designation, according to its color, form, or consistency. In later times this compound was distinguished at Rammelsberg as furnace calamine—*ofenbruch*—when it was discovered that it could be employed instead of native calamine in the manufacture of brass. Another substance called *TUTIA*, which seems to have been analogous to *cadmia*, or at least to have been a compound also rich in oxide of zinc, is spoken of in writings of the eleventh and subsequent centuries as having been employed for the manufacture of brass. ZOZIMUS, who is supposed to have written about the fifth century, states, that to make brass, cyprus copper must be melted and pounded *tutia* strewn upon it. According to ALBERTUS MAGNUS, the celebrated alchemist HERMES taught the method of making copper of a gold color by introducing pounded *tutia* into the melted metal; and ALBERTUS leaves no doubt of the nature of this *tutia*, for he states that it is not a native mineral, but an

admixture produced in the furnace when copper ore is melted—thus showing that evidently it was a sublimed oxide of zinc mixed with other ingredients, and analogous to the furnace calamine or *ofenbruch* of a later period. The discovery that this sublimate could be substituted for native calamine in the production of brass, is said to have originated with ERASMUS EBENEZER, a German, towards the middle or first quarter of the sixteenth century. The discovery was greatly esteemed, as up to that period the refuse matter from the furnaces of Rammelsberg were cast aside as useless. Doubtless the period intervening from the time of ALBERTUS MAGNUS to that of PARACELSUS gradually developed facts resulting in a more comprehensive knowledge of *cadmia*, *tutia*, and the other substances containing oxide of zinc, and leading as a natural consequence to the isolation of the metal. Indeed, the former of these writers distinguished the principle in the earth which was used to convert copper into brass as *marcasita aurea*, a term which might be qualified as meaning the metal of this earth, though properly it was understood at the period as a mercurial ore, probably a sulphide of mercury. This *marcasita*, of which MAGNUS speaks as superior to the other ores of zinc, was found at Goslar; but that of which PARACELSUS wrote was stated to be produced at Carinthia. By AGRICOLA, however, who wrote about the year 1550, reference is made to the Goslar product alone, which he designates as *liquor candidus* or *counterfey*; and FABRICIUS, who died in 1571, conjectures that *stibium* is what the miners call *cincum*, a compound that could be melted but not hammered.

From these different statements it will be seen that the knowledge of zinc, even for a long time after its recognition as a distinct metal, was exceedingly meagre; and in point of fact very few of the chemists of that period could obtain even samples of

it, owing, as it is alleged, to the great hopes entertained of it as an alchemical agent, and the consequent prohibition by Duke JULIUS to sell it or make it generally known. However this may be, the first certain account of its production at Goslar was given in 1617 by LÖHNEYSS, whose note in reference to it runs thus:—When the people at the melting-house are employed in melting, there is formed under the furnace, in the crevices of the walls, under the stones where it is not well plastered, a metal which is called zinc or *counterfeht*, and when the walls are scraped the metal falls down into a trough to receive it. This metal has a great resemblance to tin, but it is harder and less malleable, and rings like a small bell. It is not much valued, and the servants and workmen collect it only when they are promised drink-money. They, however, scrape off more of it at one time than at another; for sometimes they collect two pounds, but at others not above two ounces. This metal by itself is of no use, as, like bismuth, it is not malleable; but when mixed with tin, it renders the latter harder and more beautiful, like English tin. This zinc or bismuth is in great request among the alchemists.

BECKMANN KENKELL is accounted to have been the first who procured it directly from calamine in 1741. After him LAWSON is stated to have succeeded in extracting it from the ore, though no account of his researches exist. VON SWAB, a Swede, obtained it by distillation from calamine in 1742; and almost contemporary with him MARGGRAF likewise discovered a process for the same purpose in 1746. It is stated by WATSON in his chemical essays, that in 1743 a manufactory for the production of this metal was established at Bristol, by CHAMPION, and was carried on by his successor, EMERSON, who established another in the neighborhood. It appears, however, that the wants of Europeans, as regards this metal, were supplied from China and India, through the Dutch, and probably the Portuguese, the imported articles bearing the title *tutenague*, or Indian tin. RAYNAL records that the Dutch East India Company purchased annually at Palimbang a million and a half pounds of this metal; and the Danish Company at Copenhagen, in 1781, as much as one hundred and fifty-three thousand nine hundred and fifty-three pounds. It appears, however, that between the above date and 1820 the production of zinc must have greatly increased, as it is recorded that at the latter date spelter or zinc was imported into England from Silesia, to be again exported to India to supply the place of the *tutenague*, formerly imported from China. The Silesian zinc was analogous in composition to the Chinese product, as will be seen by the subjoined figures:—

	Zinc.	Lead.	Iron.	Sulphur.	Sand.
Silesian zinc,	98.32	1.40	—	0.18	0.10
Chinese <i>tutenague</i> , 97.63	0.33	1.90	0.14	—	—

The quantity exported from England to India almost balanced the total amount of her imports, until about 1830, when the quantity retained for home consumption began to be increased annually, so that in 1851 the amount thus utilized reached eleven thousand two hundred and sixty-two tons, while the quantity imported in the same year amounted to eighteen

thousand six hundred and twenty-six tons, whereas the exports to India remained nearly the same. At present Silesia is the great seat of the manufacture of zinc, containing the largest works of the kind in the world, and producing as much as fifty-three per cent. of the total yield of all countries. Belgium, including more especially the works of the *Vieille Montagne* Company of Liege, ranks next, and produces about thirty-three per cent.; Poland and Cracow furnishes ten and a quarter per cent., and England the remainder.

The application of zinc within the last twelve years has been very much extended, not only for use in brass foundries, but in several other departments, such as in galvanizing iron for light roofing and for fencing, and in fact for all the lighter kinds of iron which have to be exposed to the air; for the base of electro-plated articles, for paint, and various other applications.

OCCURRENCE OF ZINC.—This metal is never found in the native or virgin state, but always combined with oxygen, sulphur, and salt radicals. Ores of zinc are met with in almost every country, though not to such an extent in many of them as to render them particularly important in a metallurgical point of view. The most remarkable deposits of these ores hitherto discovered are those in New Jersey in the United States, where almost every variety of the natural combinations of zinc are met with. They exist in considerable quantities in Siberia and on the continent of Europe, more especially in Silesia, Hungary, Carinthia, Saxony, Belgium, Sweden, and France; also in England and Scotland, and some parts of Ireland. The most famous localities where the deposits occur will be mentioned presently in specifying the particular ores of zinc.

ORES OF ZINC.—The most important ores of zinc, not only as containing more of the metallic element, but also as affording greater facilities for its extraction, are the oxide, carbonate, sulphide, and silicates.

OXIDE OF ZINC—SPARTALITE—red oxide of zinc, zinc oxide ferri-fere; zinc erze; zinkit.—Generally this ore is met with in the amorphous state, but it is occasionally found crystallized in forms of the rhombohedral system, the crystals appearing colorless or yellowish-red, according to the purity of the compound; their lustre is adamantine, appearing translucent on the edges, having a cleavage parallel to the base and one of the sides, a conchoidal fracture, and a specific gravity equal to 5.43 to 5.52. Crystallized oxide of zinc is infusible before the blowpipe, though it phosphoresces strongly; with borax and phosphorous salt the presence of manganese is indicated in it, while that of zinc is shown by the green color produced in the assay, when it is moistened with nitrate of cobalt solution, and subsequently heated to strong redness. The powdered crystals, as well as the amorphous substance, dissolves readily without effervescence in nitric acid. Its composition is—

CARBONATE OF ZINC—*calamine*; *zinc carbonaté*, *Galmei-Smithsonite*; *zinc spar*.—This is by far the most important ore of zinc, and that from which the metal is chiefly extracted; it is more diffused than any other, and offers, like the oxide, peculiar facilities for smelting. Calamine is usually found in a crystallized state, in concretioned and compact masses, and in pseudomorphic forms. The crystallized variety when pure has a vitreous, inclining to a pearly lustre; is colorless, white, grey, green, or brown, according to its freedom from extraneous matters. Its crystalline form is that of the rhombohedron, with a cleavage parallel to its faces.

Its fracture is uneven or imperfectly conchoidal; its streak white, and its specific gravity 4.34 to 4.45. The ore is infusible before the blowpipe, but affords a white sublimate of oxide of zinc when it is heated on the charcoal, and which is yellowish while hot, and becomes white on cooling. By moistening the assay with a solution of nitrate of cobalt, and then heating, the green color peculiar to zinc under such treatment makes its appearance. It is readily soluble in acids with the evolution of carbonic acid, and in an excess of caustic potassa. The following analyses of a few samples of the mineral indicate its composition:—

Very frequently the silicated oxide of zinc and the carbonate are confounded under the title calamine. Two principal classes of calamine are recognized, namely, ordinary white calamine, which may be a carbonate or a silicate of the oxide, containing but a very small proportion of ferruginous matters, and the *red*, which differs from the foregoing, but only by its containing more hydrated sesquioxide of iron or its salts.

The following are analyses of red calamine by JOHN:—

	100.00	100.00

Calamine, as well as *blende*, is found in two geological formations—the one is the carboniferous or mountain limestone, in which it occurs in veins accompanying galena; and the other the magnesian limestone formation of English geologists, the Alpine limestone of the French, and the *Zechstein* of the Germans, in which it is disseminated in small veins forming a network in the mass, not more than a few inches in thickness, except where several intersect, when it sometimes increases to

as many feet. Explorations for lead and zinc are carried on in England, wherever the mountain or metalliferous limestone exists; but the principal seats of operation are in the neighborhood of Alston Moor in Cumberland, of Castleton and Matlock in Derbyshire, and in Flintshire in Wales. In the magnesian limestone the explorations for calamine are prosecuted chiefly on the flanks of the Mendip hills, near Bristol; and the mineral is excavated by means of numerous small shafts and levels. Calamine usually occurs in beds and veins, associated with Smithsonite galena, blende, and other minerals, in the crystalline slates, transition rocks, the coal formations, the muschel kalk, and oolite formations. It is found at Altenberg and Nirm, near Aix-la-Chapelle; at Iserlohn and Brilon in Westphalia; near Tarnowitz in Silesia; at Raibel and Bleiberg in Carinthia; in the Banat; at Miedziana Gora in Poland; Dognazka, Rezbanya, and Saska, in Hungary; at Kuesiana in Servia; Tschairski in the Altai; Nertschinsk and Nischn Tagilsk in Siberia; Chessy in France; in Belgium; in several places in the United States, especially in Jefferson County, and many other localities.

SILICATE OF OXIDE OF ZINC—*Smithsonite*, Phillips; *zinc oxidé silicifère*, Hany; *zink-glas*, Hausmann; *galmei*, Haidinger.—Two varieties of this mineral exist;

the one anhydrous and the other hydrated. Anhydrous oxide of zinc is found crystallized in regular hexahedral prisms of a green or grey color; translucent, sometimes transparent, with a vitreous lustre on the surfaces of the fracture, which is somewhat conchoidal and uneven. Its streak is white. Before the blowpipe it is infusible, and is only reduced when mixed with charcoal, and submitted to a very high temperature; heated with soda on charcoal, it affords a sublimate of oxide of zinc; with a solution of nitrate of cobalt it affords the characteristic green color of zinc; it is decomposed by mineral acids, yielding a jelly of silicic acid. It is composed of—

Oxide of zinc,.....	71.32
Oxide of lead,.....	2.66
Oxide of iron,.....	0.67
Silicic acid,.....	25.35
	100.00

HYDRATED SILICATE OF ZINC—*Electric calamine.*

—Silicates of zinc, especially this variety, were long confounded with calamine or carbonate of zinc, notwithstanding the great difference which exists between the two minerals. Electric calamine occurs in stalactitic, mammillated, botroidal, and massive forms, as well as in crystals of the right rhombic system. Its usual color is white, but in this respect it varies to shades of yellow, brown, green; its lustre is vitreous, and its streak white; it is phosphorescent when rubbed, and becomes electric by heat; its streak is white; it has an uneven fracture, and a specific gravity of 3.3 to 3.6. When heated on the mattress it yields water and turns white. It swells on charcoal before the blowpipe, and shines with a green light, but does not fuse, excepting a little on the edges; in other respects it comports itself like the anhydrous compound. The pure silicate is composed of—

Oxide of zinc,.....	67.07
Silicic acid,.....	25.48
Water,.....	7.45
	100.00

corresponding to the formula $\text{ZnO}, 2 \text{SiO}_2 \text{HO}$. In most cases, however, this mineral is associated with various extraneous matters, as shown in the annexed analyses—

Numbers 1 and 2 in the foregoing table were from Limburg, 3 from Breigau, 4 from Rezbanya, and 5 from Leadhills.

This mineral is generally associated with calamine in veins containing iron and lead ores and blende; it is found in most of the localities already mentioned as containing calamine. Considerable quantities of it are mined at Bleyberg and Raibel in Carinthia; in Brisgau, Hungary; and at Tarnowitz in Silesia; it is also found in Poland, Galicia, Baden, in the Tyrol, and in Banat; at Alcares in Spain; at Altenberg, near Aix-la-Chapelle; at Moresnet, near Liege; near Goslar in the Hartz; at Matlock, Derbyshire; in the Mendip Hills and Flintshire in England; at the Wanlock-head; and the Leadhills in Scotland, and several other localities.

SULPHIDE OF ZINC—*Blende; zinc sulfuré; zinc-blende.*—Blende occurs in a variety of conditions—massive and crystallized in octa- and dodecahedrons and other allied forms, derived from the cubic system, its color varying between black, brown, red, yellow, and green. The crystallized variety is translucent, transparent, and opaque; it has an adamantine lustre, a conchoidal fracture, and a cleavage parallel to several of its faces; it gives a white, shading off to a reddish-brown, streak, according to its purity; it is brittle, and has a specific gravity of 4.0 to 4.1. By friction some varieties are rendered electric. Heated alone it decrepitates violently; it is infusible, excepting slightly on the edges in the blowpipe flame; but it gives, under a strong oxidizing flame, a sublimated areola of oxide of zinc round the assay; with carbonate of soda on charcoal it is reduced. When treated with nitric acid the base is dissolved, and the sulphur left in proportion to the strength of the acid employed. When pure, sulphide of zinc consists of equivalent proportions of its constituents, corresponding to the formula ZnS , and is composed centesimally of—

Zinc,.....	67.03
Sulphur,.....	32.97
	100.00

Generally, it contains several impurities, such as sulphides of iron, of lead, of cadmium, and of antimony; the first of these is more frequently met with in the dark, and the second in the reddish striated kind. The following are analyses of a few samples of blende from different localities; namely, those marked 1, 2, and 3, from Przibram; 4, a transparent variety from New Jersey; 5, from Bagnères de Luchon; 6, from Chérones, in the department of Charente; 7, from Raibel in Carinthia; 8, from Eaton; 9, from Shelburne in New Hampshire; 10, from England; and 11, from Christiania:—

Blende is found, as before stated, in the metalliferous mountain and magnesian limestone, especially in England, in veins and beds associated with lead, iron, and copper ores. In Cornwall its presence is observed in the older transition rocks, and chiefly accompanying copper pyrites. The variety so found, from the large quantity of sulphide of iron, is mostly of a black color—hence the miners term this mineral *black jack*. The ore is found in more or less abundance in Hungary, Transylvania, Bohemia, Carinthia, and the Hartz; large quantities of it are obtained in Cumberland, Derbyshire, and Cornwall, in England; Flintshire, in Wales; in Perthshire, the Leadhills, and the coal fields round Edinburgh and Lanarkshire, in Scotland.

SULPHATE OF ZINC.—*Goslarite, zinkvitriol, white vitriol, aluminate of zinc, gahnite spinelle, zincifère*, and a few other minerals of zinc exist; but their importance in relation to their abundance, or for their application in the metallurgy of zinc, is not so great as to require a description here.

PREPARATION OF ZINC.—To obtain perfectly pure zinc is a task of some difficulty, so much so that the commercial article is never met with in a pure state, but rather with variable quantities of arsenic, cadmium, tin, lead, manganese, iron, cobalt, and nickel. In order to obtain perfectly pure metal, the purest commercial zinc should be dissolved in dilute sulphuric acid, filtered from any residue, and the foreign metals thrown down by immersing plates of zinc in the liquid till no further deposit takes place. After separating the precipitated metals, which may be tin, lead, copper, cadmium, antimony, and a trace of arsenic, the solution is treated with carbonate of soda, and the carbonate of zinc, which falls after filtration and thorough washing, is dried, heated to redness to expel carbonic acid, mixed with charcoal or lampblack, and introduced into a crucible as represented in Fig. 623, placed in a furnace,

Fig. 623.

and the metal reduced and recovered by the method known as distillation *per descensum*. In this figure, the crucible wherein the mixture of carbonate and charcoal is placed, is shown by A; it rests upon a disc of clay, B, which, together with the bottom of the crucible, is perforated for the purpose of passing a clay tube through both, one end of which opens at the top of the crucible near the cover, and the other dips into a cup of water, C, placed beneath the grate and ash-pit. The crucible being fixed, with its charge and its cover closely luted with clay, is placed in the furnace and heated to whiteness, when the reduced particles of the metal pass off in vapor, which finds an outlet in the lower opening of the tube, and condenses in the cup of water in grains. The zinc obtained in this way will be very pure, but to obtain it in absolute purity, it is necessary to have recourse to electrolysis from a solution of zinc which has undergone the above-

mentioned purifying operation, and from which the iron, manganese, and other bodies which may be deposited on the electrode, are separated by treatment with an excess of caustic potassa, subsequent precipitation of the zinc as carbonate, washing, and re-solution. The distillation of zinc being always conducted at a white heat, a repetition of the distillation, however often repeated, is not sufficient to separate many impurities of a metallic nature, which greatly injure its properties, and prevent its applications in many operations of a chemical and manufacturing nature. The substances with which it is most liable to be contaminated when prepared in this way, are lead, tin, antimony, cadmium, and arsenic, as these metals evaporate with the zinc and alloy themselves with it. A simple process adopted to free zinc from several of the preceding metals consists in incorporating some sulphur alone or mixed with grease in the melted metal, and stirring the whole rapidly with a wooden slip. The foreign metals are by this operation converted into sulphides, but traces of them are still retained in the melted zinc. Another method is to granulate the zinc by melting it in a crucible, and pouring it while fluid into a tub of water, then mixing the powder with a quarter of its weight of nitre, and introducing the mixture into a crucible, taking care that a portion of the salt rests beneath and upon the metal. The crucible is then heated in a furnace till vivid combustion ensues, after which it is taken from the fire, the slag removed from the surface, and the melted metal poured into water. Arsenic and iron are thus removed.

PROPERTIES OF ZINC.—When pure, this metal has a bluish white color, somewhat similar to lead or aluminium, and a strong metallic lustre. It crystallizes in long regular hexagonal prisms, according to NAGGERATH, but others give the crystalline form as cubic prisms. NICKLES asserts that zinc distilled in an atmosphere of hydrogen forms well-defined pentagonal dodecahedrons on cooling. When freshly fractured, its crystalline texture is lamellar, the plates sometimes appearing of considerable size. At ordinary temperatures it is brittle, of a moderate hardness, and difficult to file, but when heated between 212° and 300° it acquires a considerable degree of malleability, so that it can be drawn into wire or rolled into thin bands and sheets. Mr. FORD of Coalbrook Dale, who, according to GRAY, was the first person in England who employed the metal in casting fire-engine cylinders, states that, by the mere warmth of the hand, the strips of metal which were as brittle as glass at the ordinary temperature, could be wound round the finger like slips of paper. If the heat be raised to 400° or 410° its ductility is destroyed, and it becomes so brittle as to be reduced to powder in a mortar by ordinary grinding processes. Zinc emits a peculiar odor when rubbed. Its density, according to the mean of several experiments of BRISSON, KARSTEN, PLAYFAIR, and JOULE, is 6.89; the melted metal after cooling gave JOULE only 6.54. It fuses at 705° according to GUYTON MORVEAU, but DANIELL gives the fusing point 774°; at white heat it boils, emitting vapors which burn in the air or in oxygen gas with a very brilliant white light, producing oxide of zinc, which

condenses in filamentous flocks on a cold surface held over the flame, or on the walls of the crucible in which the combustion is effected; this is the *philosophical wool*, the *flowers of zinc*, or *pompholyx* of the old chemists. At a red heat zinc decomposes water, setting free the hydrogen of the vapor; the same effect is produced at ordinary temperatures under the influence of weak acids, and with considerably greater energy than by heat alone. In the latter behavior a remarkable difference is manifested when pure and commercial zinc are submitted to the action of the same acid, the former dissolving so slowly that it requires the action to be continued for a period of eight days to produce the same effect as that which is effected upon the latter in a space of one hour. This behavior was made the subject of a careful investigation by DE LA RIVE, who found that the action of the acid is increased by the presence of certain proportions of many metals. By alloying nine parts of pure zinc with one part of the several metals mentioned below, and employing dilute sulphuric acid, he found that the effect of the acid, measured by the volume of hydrogen disengaged in equal times, stood in the relation of the annexed numbers:—

	Gas disengaged.
Commercial zinc and alloys of zinc and iron, ..	100
Alloy of zinc and copper,	43
Alloy of zinc and lead,	15
Alloy of zinc and tin,	12
Distilled zinc,	5

One twentieth of the quantity of iron alloyed with zinc is sufficient to produce an effect equal to that of commercial zinc, and even a spiral of platinum round a bar of zinc was found to increase the action of the acid considerably. On the other hand, he observed that the acid which effected the most rapid solution of the metal, was a mixture of thirty-three parts of sulphuric acid and one hundred of water. The consideration that the zinc, on being alloyed with any metal, constitutes a kind of battery within itself, and the knowledge that the above acid is the one which possesses the greatest power of conducting electricity, led M. DE LA RIVE to the conclusion that the greater or less energy with which a plate or bar of zinc decomposes water, is dependent upon the galvanic effect of the metals associated with the zinc and of the acid body employed.

Zinc abstracts oxygen from a great number of acids containing this element. Boiling solutions of potassa and soda likewise oxidize it with disengagement of hydrogen, the oxide of zinc formed dissolving in the alkali, and forming probably the radical of an alkaline salt. Exposure to dry air, however long continued, is insufficient to tarnish bright metallic zinc; but when moisture is present it readily undergoes oxidation, a whitish coating forming upon it; this, however, retards to a great degree its further corrosion by atmospheric influences, so that it resists exposure very well; and hence, its very extended use in roofing and other applications where iron would soon become oxidized and worn away. Zinc forms an extended class of salts with acids, many of which are of some importance in many departments of art and manufactures as well as in medicine, and the metal itself has of late years been applied to a great many important uses. Zinc has the

atomic or combining number 32; and its symbol, or chemical formula, is Zn.

METALLURGY OF ZINC.—The principal places for the production and manufacture of zinc are, in England, Swansea, Carlisle, Bristol, Birmingham, and the neighborhood of Sheffield; Flintshire in Wales; Upper Silesia in Germany; and Vieille Montagne in Belgium. The latter establishment has considerably increased during the last twelve years, but it has not attained the magnitude of the Silesian works, which are the largest of the kind in the world.

ENGLISH PROCESS.—The ores which are principally employed at Bristol and Birmingham, are those from the Mendip Hills and from Flintshire, while the Sheffield furnaces derive their stock from Alston Moor in Cumberland, and from Derbyshire. A large quantity of blende is likewise obtained from Cornwall, which is submitted to a preparatory roasting. The ore is sorted, and any blende which may be mixed with it is separated from the calamine; the latter is sometimes ground under head rollers, and roasted in a reverberatory furnace, to expel all its moisture and carbonic acid. This preparatory roasting is not universally practised, however, as some smelters merely break it up into fragments about the size of a pigeon's egg, and in this state mix it with its bulk of coal or slack, and submit it to the reduction process. Blende is always roasted before reducing it to metal, for which purpose it is sorted and broken up into small pieces of about half a cubic inch, and introduced into a reverberatory furnace, where it is roasted during ten to twelve hours without intermission. The furnace is ten feet long, eight feet wide, a half foot between the bed and the roof in the middle, and one foot and a half at the bridge. A continual rabbling is given to the ore, which is spread on the bed to the depth of four or five inches. During the period of the roasting, the ore suffers a loss of twenty per cent. from the sulphur expelled. Four tons of coal are said to be consumed during each operation. The charge for reduction is then compounded of one part of calcined blende, one part of roasted calamine, and two parts of charcoal. In the English system, the furnaces shown in the annexed figures are employed; their peculiar feature is their being adapted to the practice of the system of distillation *per descensum*. They consist, as shown in Fig. 624, of an inner cupola, A A, enclosing a double row of crucibles, G G, the whole enclosed by a hovel or conical brickwork chimney, D, similar to that of a glass furnace or pottery kiln. A number of openings, B B, are constructed in the cupola corresponding to the number of pots in the furnace, and which serves to charge and secure the pots in their places when necessary. For the convenience of the workmen the outer cone has doors, C C, before each pot. A fire, F, runs across the centre of the hearth and heats the row of four pots on either side, the smoke and gases passing off by the apertures, B B, and outwards at the mouth of the cone, D. The ash from the grate falls into the pit, E, at either side of which, and beneath the pots, is a gallery, H, where a number of dishes or other vessels are placed for collecting the zinc, conducted to them by iron pipes, having one end inserted into the aperture in the bottom of the pot, while the other

dips into the dish already mentioned. To charge the furnace, the crucibles, which are previously heated to redness in a reverberatory furnace, are carried by a pair of large iron pincers, slung in chains, and supported on a kind of over-head railway—Figs. 624, 625—much in the same way as glass-pots are inserted

Fig. 624.

and withdrawn from the furnace. They are then introduced by means of an aperture in the side of the dome, and placed in their position beneath the apertures in the top, so as to rest on each side of the wall

Fig. 625.

of the furrow opening into the chamber, H. The charge for each pot or crucible is composed of equal bulks of ore and slack when calamine either crude or roasted is used, or if a mixture of calcined blende and calamine be employed; these, in the proportions already stated, are introduced through the apertures in the dome, the outlet in the bottom of the pot being secured by a plug of wood. The fire is then urged till the contents of the pots are brought to a full red heat, approaching to whiteness, and when the vapors arising from the ore are observed to burn

with a white light, the covers are placed upon the several pots and well luted, the pipes are likewise inserted in the bottom, and the distillation is allowed to proceed, the temperature being always maintained at a high white heat. To prevent the materials in the pot from falling through, the end of the pipe is plugged with wood, but as it becomes charred, it offers sufficient space for the metal, in its passage downwards, to percolate through it without allowing any grosser matters to descend. Any metal condensed in the pipes is removed by introducing, from time to time, a small iron rod or wire, which clears it away; if this operation be neglected, the outlets are apt to get clogged up, and the tension of the enclosed gases will endanger the explosion of the covers. Usually the period occupied in a single distillation is about sixty-six hours, or five distillations in fourteen days, in which from eight to ten tons of ore are worked off, with a consumption of twenty to twenty-five tons of coal. The metal obtained amounts to thirty-five or forty per cent. of the calcined ore employed. When no more metal is condensed, the refuse matter in the pots is discharged by removing the pipe in the bottom and the cover, and then raking it out through the bottom aperture; after this operation the latter is plugged, to prepare the retort for receiving another charge. Each pot serves to distil about forty charges before it gets broken; when this happens, the fragments are withdrawn through an opening made in the surrounding brickwork, and the place of the broken pot is supplied by another annealed at a red heat in a reverberatory, as mentioned above. The collected product of the distillation, which is chiefly in drops and fine metallic powder mixed with some oxide of zinc, is melted in a large iron pot set in brickwork, and heated by a fire beneath it, when the lighter oxide and other impurities form a scum on the surface of the bath of melted metal; the former is skimmed off, and the latter cast into bars or cakes, in which state it is sent to market.

PROCESS PRACTISED AT VIELLE MONTAGNE.—The mineral wrought at this establishment is a mixture of calamine and oxide of zinc, which is of a very compact and crystalline nature, intermixed with a gangue of clay in amorphous masses. As a preparatory operation, the mineral substance, as taken from the mine, is exposed to the air for the purpose of allowing the gangue to disintegrate, with the view of rendering its separation more easy and complete in the preparatory process to which it is submitted. There are two varieties of the carbonate treated, one of a reddish color, containing a considerable amount of iron; the other white and more compact. The ore is placed in heaps, and turned over from time to time to permit the air to pass through it more freely. After a period, varying from three to twelve months, the heap is picked, and the fragments of pure ore of the size of pigeons' eggs are selected from the rest. The refuse matter is then screened, and the coarser portions again picked out by hand; finally, the reduced fragments are washed upon the inclined plane, and the chief part of the clay is thus removed. There is a considerable difference between the periods required to disintegrate the two varieties of the mineral: by a

three months' exposure the red kind is sufficiently decomposed to part with the most of its impurities, whereas the white variety takes from nine to twelve months to effect the same change; in the former the loss averages fifteen per cent., whilst in the latter it often amounts to fifty. The selected ore is then calcined, sometimes in a reverberatory, but more frequently in a conical kiln, somewhat similar in form to that in which lime is burned, and which has the advantage of being continuous in its operation. Fig. 626 represents this kiln: it is heated by two lateral fires inclosed within an arch, the products of combus-

Fig. 626.

tion from which are draughted into the interior from a channel or flue by twenty different apertures, *o, o, o*, at various points of elevation. The bottom of the kiln inclines towards the drawing doors, *A, A*, owing to the two cast-iron plates of which it is composed, *f, f*, being laid together at an angle of 45°, and hence the descending body of calcined ore falls in almost equal portions towards each of the rectangular outlets already mentioned. Coal is preferred for heating in this case, owing to the high temperature necessary to calcine the mass of ore which is introduced at regular intervals at the top. After drawing out the roasted ore it is ground under headstones, and sifted, so that its fineness is insured; it is then mixed with its proper quantity of combustible matter, which may be charcoal or fine coal, and introduced into the retorts for smelting. These retorts consist of cylinders of refractory clay, closed at the end which is inserted into the furnace, and open at that one which protrudes; to this end is adapted another cylinder of sheet-iron of a conical form, for the purpose of condensing the metallic vapor, and this in turn has a third pipe of the same form, but much smaller, appended to it. These several parts are seen in Fig. 627, *A* being the retort, *B* the condenser, and *C* the outer cone;

Fig. 627.

the first is three feet eight inches in length, and six inches in diameter, the second is sixteen inches in length, and the third about the same, only that both taper, so that the aperture of the apex of *C* is not greater than three-fourths to one inch in diameter. These are placed in a peculiar kind of furnace represented in elevated section in Figs. 628 and 629, the

latter in the line *A B* of the former. The stack consists of four distinct furnaces, each in the form of a semi-cylindrical chamber, eight feet eight inches from the highest point of the arched roof to the floor, the back of the chamber being constructed so as to recede slightly from the bottom or floor upwards, as shown by *b d*, in Fig. 629, and the front, *a c*, being left open for the convenience of introducing the retorts. The fire which heats the chamber and its complement of retorts is shown at *F*, and is placed beneath the level of the floor of the smelting house, the combustible gases and other products passing upwards through four apertures in the grate, shown at *e, e, e, e*, and thence by a double flue, *G, G*, finding an exit overhead into the chimney, *C*. The latter forms one massive construction, embracing the four outlets, each closed by a damper. In each of the chamber furnaces forty-two retorts, *G, G*, are heated; these being placed in rows one above the other, as shown in the drawing, the posterior end resting upon a ledge made for the purpose in the masonry or brickwork. In the front the distillatory cylinders are supported by plates of cast-iron, so fixed at each side of the face of the furnace as to allow the cylinders to slope downwards from the back to the front. Before placing the retorts in this furnace, a brisk fire is maintained in it for some time, so as to bring the interior to a bright red or white heat, the face of the furnace being built up with bricks or fragments of broken retorts. When this condition has been attained, the cylinders, which should be previously heated to redness in a reverberatory, are fixed in their places one by one, the interstices between each retort at the front being closed up with fire-clay. At first, a small quantity of the mixture of ore and coal is submitted to reduction in the cylinders, the condensing cone and adapter attached and luted, and any metal given out collected in the manner presently to be indicated. These preliminary charges are successively increased for a period of three or four days, or until the furnace is found to be in a proper working condition. At this period the charge attains its mean, and consists of one thousand one hundred pounds of the roasted, ground, and sifted calamine, intimately mixed with five hundred and fifty pounds of bituminous coal in fine powder, for the forty-two retorts. This is introduced into the clay cylinders by means of a long half-cylindrical shovel attached to a long iron handle, commencing with the lower retorts, and proceeding to the higher ones in succession. When all are filled, the flue, which is usually stopped by having the damper down, is

opened, and an increased firing resorted to. As the contents of the retorts attain a strong red heat approaching to whiteness, they evolve a considerable amount of carbonic oxide, which burns at the mouth of the cylinders with a bluish flame; after a while the appearance of

the flame becomes more brilliant, and of a greenish white, showing that portions of the zinc vapor have been volatilized. As soon as this symptom is observed, the iron condensing tubes are attached to the open end of the retorts, the joining is well luted with refractory clay, and finally the adapters being fixed upon the condensers and luted likewise, the distillation and recovery

of the zinc are proceeded with. Every attention is now given to equalize the heat in the interior of the furnace, in order that the upper retorts may be worked off equally well with the lower ones; but this result can

seldom be exactly attained, and to compensate for this defect the more easily reducible ores are charged into the upper retorts, and the more refractory into the lower ones, where the heat is greatest. At intervals

Fig. 625

Fig. 626

of two hours after the distillation commences, the outer adapter is removed by means of tongs, and the oxide of zinc, or *cadmia*, collected in it is removed, to be again submitted to the retorts in a succeeding charge. An assistant then holds a large iron ladle, called a *poëlon*, under the mouth of the condenser pipe, and the smelter rakes out the fluid zinc at the bottom of it, as well as the drops of metal attached to the sides and other parts. After carefully separating the oxide of zinc which covers the metal thus abstracted, the latter is cast into ingots, weighing from seventy-five to eighty-five pounds. The adapters are then replaced and secured as before, and after two hours the zinc produced is again removed in the manner stated.

A charge of ore commenced at six in the morning, and worked in this way, is found to be exhausted of its reducible metal at five in the afternoon, so that two charges are worked in the twenty-four hours. When one operation is finished, the adapters, con-

densers, and retorts are thoroughly cleansed and scraped out before the next charge is introduced; and the oxide resulting from every operation and collected from the adapters and skimmings, is worked up as part of the ore of the preceding charge. The argillaceous residue cleared out of the retorts after the distillation has ended, is found to contain as much as ten per cent. of zinc; but being in the form of silicate of oxide, it resists the action of the charcoal and remains intact. About thirty per cent. of the calamine submitted to reduction is obtained in the form of metal. The distilling campaign lasts two months, during which time the fires are maintained at their greatest activity consistent with the work to be accomplished. At the end of this period, the necessity for repairs and replacing old retorts compels a cessation of the smelting for the time required to effect the necessary renovation.

Process for the Smelting of Zinc Ores in Upper Silesia.—The ores of zinc worked in this district

are principally a carbonate mixed with some oxide, having a calcareous and argillaceous gangue; and as

Fig. 630.

the latter ingredients would materially impede the reduction of the principal compound, the oxide of zinc,

Fig. 631.

they are as far as possible removed by processes of disintegration and washing analogous to those already mentioned in connection with the Belgian method.

As in the English and last mentioned smelting establishments, the purified calamine is here submitted to a preparatory calcination for the purpose of expelling the water and carbonic acid. The furnace used for this purpose is shown in Figs. 630 and 631. It consists of an ordinary reverberatory, of which *a* is the fire-grate, *b* the doors by which the fuel is introduced, *c* the fire-bridge, *d* the interior of the furnace, the bed of which is constructed of ordinary bricks, *e e* the working doors by which the charge is rabbled and worked during the calcination, *f* the flue leading to the chimney, and *g* the superior aperture whereby the ore is charged upon the bed of the furnace. The latter is lighted in the usual way, and as soon as the interior attains a strong red heat, from thirty to thirty-five hundredweight of ore are introduced at *g*, the workmen spreading it out upon the sole with rakes at the working doors; this done all the openings are closed, and the roasting is allowed to proceed uninterruptedly, with the exception of an hourly rabbling for the purpose of exposing a fresh surface of ore to the flame, till the whole of the moisture and carbonic acid is expelled. The completion of the work is judged of by the apparent heat of the interior of the

furnace, the facility with which the ore falls to powder, and its change of color, which in case of the red calamine being operated upon should be brownish, and of the white calamine brownish-red. When these appearances are observed the charge is drawn, and a second, which had been placed on the platform in the interval between the charging and drawing of the roasted ore, introduced in its stead, the largest fragments from the last operation being ground and added to the fresh ore to be recalcined. Four charges are thus treated in the twenty-four hours, making a total of nearly six and a half tons of ore, which yield about seventy-two hundredweight of calcined calamine, with a consumption on an average of twenty-three bushels of fuel.

The Carinthian Process.—Here the furnaces are worked on the same principle as the English ones, but the details are different:—Figs. 632 and 633 show a plan and sectional elevation of the Carinthian furnace. As at the *Vieille Montagne* smelting works, four furnaces are connected in one block with one chimney; they consist of rectangular chambers arched over at the top, *b b b b*, heated by fires, *a a a*, from which the heated gases and flame enter by openings, *a' a'*, to the space occupied by the retorts. Above the sole of the retort chamber, *b*, is placed a trellace work of iron, in the squares of which the vertical retorts, *p p*, are fixed by means of a clay conductor, *n*, which receives the zinc separated in the vertical cylinder. *c c c c* are the side doors affording ingress for placing the conductors and retorts in position for operations, *et cetera*; *d d*, outlets for the waste gases from the furnace into the flues, *e e e e*, leading to the chimney, *h*. Beneath the conductors, *n n*, is placed a flooring of plate-iron, *r r*,

Fig. 632.

resting on cross supports, as well for receiving the zinc which falls in the course of the distillation as for excluding the atmosphere, and thereby preventing

the reoxidation of the metal. Each of the distilling compartments admits of erecting one hundred and sixty-four vertical retorts with their conductors, but the four ranges more distant from the heat contain only

Fig. 633.

Fig. 634.

Fig. 635.

empty cylinders in process of being baked by the waste heat; and even for those within the range of a distilling temperature a different mixture is made for the charging according as the cylinders are nearer to or more distant from the fire. This mixture has the following composition:—

	For the four ranges nearest the fire.	For the other two ranges.
Roasted calamine,.....	1820 lbs.	520 lbs.
Wood charcoal, ground,.....	504 lbs.	224 lbs.
Common salt,.....	36 lbs.	16 lbs.
Water charged with 1-200ths of potassa, 280 lbs.		70 lbs.

The four first ranges contain sixty-four cylinders, whereas the following two contain but twenty; the remaining spaces being left free for the passage of the products of combustion. Two adjoining furnaces are always worked together, and in these one hundred and sixty-eight cones are in operation. During the course of the distillation, which occupies thirty to thirty-six hours, the consumption of wood as fuel amounts to seven hundred and fifty cubic feet, and the proceeds average eight hundred pounds of metallic zinc.

Considerable loss of time, fuel, and retorts is incurred from the intermittent nature of the process. After collecting the metal which falls upon the plate-iron flooring, indicated by *rr*, in the foregoing figures, it is refined from oxide and other grosser impurities by fusion in pots placed in a furnace, represented in plan and section in Figs. 634 and 635. After melting the metal in the series of pots shown in these furnaces, the scum of oxide, carbonaceous matters, *et cetera*, rises to the surface, and is removed by the ladle, and the purified metal is cast into moulds for the market.

Silesian Method.—In Upper Silesia the reduction of zinc ores is carried on by a distilling process in a muffled furnace, as will be described presently. The principal seat of the smelting is in Silesia, where, in 1848, there were no fewer than thirty-five establishments for the distillation of the metal. In the Rhine Province, at the same period, there were five, and in Westphalia one. With the growing demand for zinc, however, these establishments have, during the last ten years, been enlarged and rendered more effective, so that

Fig. 636.

Fig. 637.

their capacity for working is greatly increased. It may be remarked that the *materiel* of the muffles consists of fire-clay, obtained from Ruda Krzeszowitz and Kattowitz in Upper Silesia, as also from Murau

in Poland, and which, after the necessary preparation, is mixed with reduced broken muffles, the whole being properly blended together to give the articles the necessary cohesion and compactness. The proportion of clay and potsherds is invariably two of the former to one part of the latter. These muffles are always made by hand, and submitted to a gradual course of

desiccation, then annealed at first at a very moderate temperature, and finally at a full red heat in a furnace especially constructed for the purpose, somewhat in the manner of making glass-pots.

Figs. 636, 637, 638, 639, 640, represent the ordinary furnaces, called *double ovens*, adopted in Upper Silesia for the reduction and distillation of zinc from its ores.

Fig. 638.

Fig. 639.

They have ten primary large chambers; but these in working are divided into twenty smaller parts, the large muffles being so constructed that the back wall is common to the two ranges. Fig. 636, is a section representing a longitudinal view to the left hand, following the line A B, and to the right the line C D in Fig. 637. Fig. 638 shows a ground plan at $a' b' c' d'$ in Fig. 636, and $d'' d''$ in Fig. 637, in the upper half of the left side, and in the under half at $a' b' c' e'$ in Fig. 636, and $e'' e''$ in Fig. 637. The portion to the right

exhibits the furnace vertically under the dome. The same letters indicate like objects in the several figures. Three triangular cast-iron bars, $a a a$, secured at each end in the walls of the furnace, bear four iron plates, $b b$, laid transversely, to form the fire grate; the whole constituting a rose over the air channel and ash-pit. The fire-door, c , which is lined near the grate with a cast-iron box, d , is closed with a door of plate-iron, the sole of the aperture being likewise secured by a similar plate; $e e$, *et cetera*, are inclosed troughs, into

Fig. 640.

which the distilled zinc trickles from the apertures of the retorts. The base of these is of iron plates, $f f$, to which deep iron bands are fixed for preventing the overflowing of the metal as it falls from the mouths of the retorts opening into them. All these receivers are closed by a single plate, $g g$, extending the whole

length of the oven, and called the *hearth-plate*. They are but one foot wide, and protect, therefore, only the front part of the receivers; the interior of the latter being secured by supplementary closely fitting plates, $h h$, touching the hind part of the openings, $i i$, and towards which is the connection between the dropping aper-

tures and receivers. These hearth-plates, in order that they may not be warped by the heat, are fastened by three cast-iron fluted anchors of the form of the letter Z. The walls, *l*, of the fire-chamber are constructed of the best fire-bricks; the connection between the fire and fire-door being an inclined canal, *m*. The upper rim of the fire-chamber is a few inches higher than the receiving troughs, so that the hearth slightly inclines from the middle to the side walls of the oven. The space between the posterior walls of the two adjoining ovens is filled with sand and rubbish; *nn* are side draughts for heating the rim muffles, and *oo* horizontal entrances for cleaning the same, which, however, are closed during the firing; *ppp*, *et cetera*, are pillars from three to five inches in thickness, constructed of clay, and furnished exteriorly with iron plates, *q*, secured to the hearth-plates, *gg*. These pillars form the support of the arches of the muffles which receive the retorts, as also of the overspanning dome. They should be as low as possible, so that the distance from the apices of the interior arches and the hearth be not more than three feet. The dome of the oven is constructed of a composition consisting of one-third part clay and two-thirds sand; its thickness when dry is eight or nine inches; *rr* are six cap or draught holes, by opening or closing which the heat can be directed towards any of the retorts which should happen to be working unsatisfactorily; *ss* hinges or clasps for fastening the doors, *tt*; *u* long bracing bars or anchors; *v* oblique ones, and *w* upright anchors, all applied for the purpose of giving solidity to the oven.

The retorts or muffles, *xx*, are set two and two within the muffle arches in the spaces between the pillars, *pp*, and placed as far back as possible, with their open faces to the front. When placed in their proper positions, the spaces between their walls and the pillars are blocked up with clay cement so as to confine the flame. The mouth of the retort is closed with a piece of clay called the bridge, *y*, and shown somewhat enlarged in Fig. 641. It has two openings; the under one, *a*, closed with a clay stopper during operations, for drawing out the residuary matter of the distillation, and the upper one, *b*, for receiving the neck of the conduit by which the vapors of zinc pass to the receivers. The latter part of the apparatus is seen in Fig. 642; the under part, *a*, is a clay pipe; the upper part consists of the head, *b*, and the neck, *c*. An opening in the head of this receiver serves for introduc-

Fig. 641.

Fig. 642.

ing the small charging shovel—Fig. 643—to spread the charge within the retort. It is closed like the opening, *a*, in Fig. 642, during the distillation.

Before the muffles are placed in the distillatory oven, they are subjected to a strong red heat in the furnace

employed for annealing them. They are then placed two and two in the arched chambers of the zinc oven, and charged with a mixture of sixty-six pounds of

Fig. 643.

roasted calamine and an equal volume of cinders or small coal—forming about five per cent. of the weight of the ore—together with a few pounds of oxide of zinc and abstrich or semioxydised skimmings from the collected zinc. All these are intimately mixed together before their introduction through the upper opening of the muffle bridge, the lower aperture meantime being secured with a plate and lute of clay. When charged, the neck and condenser are fixed in their places, and all apertures and cracks safely coated with luting. The iron doors in front are closed to retain the heat, and the firing proceeded with. Scarcely a quarter of an hour after the closing of the front doors of the muffles elapses when the metal begins to pass over; nevertheless the distillation is not in full activity till six to eight hours after commencing. As in the other distillatory processes already described so in this: the zinc, deprived of its oxygen by the coal in the body of the retort, passes off into the neck and head of the conduit in the form of vapor, and then condensing falls through the descending pipe into the plate-iron receivers. The combustion of a portion of the zinc cannot be avoided, as it is impossible to prevent the admission of some air into the receivers and conduits. It is owing to this, that a portion of white oxide is always found in the receivers, averaging from two to four per cent. of the metal obtained. At the close of twelve hours all the metal is extracted, and a second charge is introduced, without, however, clearing out the residue in the retort until at the end of the second operation, at which period a new bridge plate may be supplied if necessary, or any other repairs made. Care should be taken to change the muffles of both working sides of the oven every six hours after their setting in.

When the calamine contains much cadmium, it is found that the first portions of the distillate are very rich in this metal; and the oxide produced by the combustion of portions of the metal in the neck of the retort is likewise richer in oxide of cadmium, both effects being due to the volatility of the cadmium being greater than that of zinc. Six hundred pounds of roasted calamine are worked off by a furnace of ten large muffles in twenty-four hours, with charges for each retort averaging six pounds. The estimated consumption of coal per every hundred of zinc obtained is twenty-eight cubic feet; the loss of the metal is estimated at eight per cent., and of large muffles twenty-eight for every thousand pounds of zinc obtained. The average produce from the calamine operated on is about fifty per cent. in the form of metal and oxide. But as the ore varies in its content of oxide of zinc, so also does the yield. To purify the metal resulting from the first distillation, it is melted in iron

pots, and the scum of oxide and other impurities separated. This amounts to eight per cent. ; but as it contains about seventy per cent. of metal, and is submitted to a new reduction, a considerable amount of it is recovered.

At Kloster, where blende is worked, the apparatus and system of reduction are the same as that just described, with the exception of the roasting furnaces, in which the sulphide of zinc is converted into oxide. These are also the same as those that have been previously described, and consequently need not be further referred to.

PATENT PROCESSES.—The only patents connected with the manufacture of zinc which are of any importance, are those of TROUGHTON and GRAHAM; the former sealed in 1839, and the latter in 1845. Other patents have been secured, but the Editor deems it unnecessary to dwell upon them.

TROUGHTON's patent professed to deal with blende, and prescribes a form of furnace for the roasting, as also for the reduction. The first of these is in form like an ordinary reverberatory, with, however, three floors or hearths, on each of which the ore is spread, the heated gases and flame passing from the under chamber into the middle, and thence to the upper one, after which the gases proceed into the chimney. The connection between the several floors is made by apertures, covered by fire tiles during the roasting, but which are removed when it is necessary to transfer the ore through these openings from the upper to the lower ones. By apertures at the sides the contents of each floor are rabbled in the usual way. The charging of the ore is effected through hoppers at the top, and when roasted it is raked out into receptacles beneath the lowest hearth, by the workable openings already mentioned. A close fire, charged with fuel, which may be anthracite coal, and urged by a blast, affords the requisite heat; the opening for introducing the fuel being secured by a cast-iron cover, with a flange descending into a groove which may be kept filled with water or sand to prevent the escape of hot gases.

The fire by which the smelting of the roasted ore is effected is similarly constructed, and the combustion maintained by a blast of hot air. Though the plan as detailed in the English system is followed, yet the details are very different; the receptacles for the reception of the roasted ore and coal are constructed in the form of a trapezoid, the front part being movable when it is necessary to charge or clean out the retorts; but during the distillation it is securely luted in its place. Two ranges of retorts are placed back to back in a gallery, and the heat from the fire conducted beneath and over them by a proper disposition of the flue; and for the purpose of economizing heat, the patentee directs that the retorts be so fixed that they may be heated by a fire from both ends of the gallery. A pipe opening into the retorts, and leading to receivers in a confined arch beneath the hearth, serves to carry off the distillate or zinc. When charged and in working condition, the retorts are closed in by an iron door before each; the space above the retorts wherein the ore is previously heated, is likewise approached by sliding doors, with the view of

rendering the introduction of ore and its withdrawal more easy.

In GRAHAM's patents, sealed in 1844 and 1845, the system of distillation *per descensum* is adopted; improvements being claimed for the arrangement of the apparatus and furnace, as well as for the method of making the cylinders or retorts in which the decomposition of the prepared ore is carried out. The mixture which the patentee finds most suitable for the body of the refractory cylinders just mentioned, consists of one and a half hundredweight of Ceylon black lead; six hundredweight of Stourbridge clay; and one hundredweight of potsherds. These ingredients should be well pugged and tempered, and cut into pieces of convenient size, care being taken that no excess of moisture be used that would prevent the proper cohesion and tenacity of the mass when ramming it into the mould. Fig. 644 represents the furnace and the position of the cylinders and other objects. A, A, are a series of pots, of which the number shown in the furnace is sixteen, but more or less may be employed, according to circumstances. The heat from the fireplaces, B, B, enters into the

Fig. 644.

arched chambers, C, C, and circulates round the cylindrical retorts let down through the arches, D, D, and thence into the flues, as shown by the arrows, and finally by the openings, F, F, into the chimney. The pots, A, A, rise above the arches, D, D, and pass through the covering of brickwork, E; in like manner their outlet penetrates the bed of the arched chamber of the furnace, and opens into the receivers, G, G, beneath, through movable pipes, J, J, and stationary ones, I, I, the latter are constructed of iron and lined with clay, or have a movable clay cylinder fixed within them; they have an iron flange of two inches built in and through the bed of the furnace, in which is a projecting ring or groove, Z, Z, to receive an iron ring that forms the projecting rim just referred to, and which fits into a corresponding depression in the bottom of the pot, and thereby forms, with the aid of a little luting, a tight joint. Y, Y are rings made of fireclay and potsherds, built into the bed of the furnace, flush on the outside, leaving a space of one inch and a half inside, as shown, to form a seat for the pot. W, W are holes in the walls of the furnace, which admit of making an inspection of the pots when necessary.

In charging the pots, the pipe, J, is stopped from

beneath the furnace, and a man holds steady the internal tube, H—which has its top covered—until some of the charge is introduced; the remainder is then filled in without fear of disturbing the position of the pipe. The cover is now placed on the pot and luted, and the plug securing the pipe, J, withdrawn, and the distillation allowed to proceed by urging the fires, B, B, B. When all the metal has been drawn off, the refuse matter remaining in the pots may be cleared away by removing the cover and the internal pipe, and poking it out through the pipe, J, into the subjacent chamber.

In the other details the directions which the patentee gives are analogous to the general routine, already sufficiently described.

Mr. CROCKFORD of Holywell, Flintshire, has latterly patented a method of roasting blende preparatory to its smelting, by which all the sulphur is obtained as sulphuric acid. This he effects by employing a furnace the heat of which passes beneath the floor on which the powdered blende rests. At one end of this furnace, the blende is continually introduced in small portions at a time; and in its passage from this to the discharging end of the chamber, in addition to the heat from the floor, it is acted upon by a current of superheated air, in order to convert the sulphur into sulphurous acid. The eliminated gases may be conducted into an ordinary leaden chamber, and nitrous vapor and steam supplied from other departments in the usual way, to convert them to sulphuric acid.

After the depuration of the zinc distilled from the ore it is sold to the manufacturer, or immediately applied to one or other of the many purposes for which this metal is now so generally used. The working of zinc into useful articles was formerly regarded as a difficult operation, owing to its brittleness when worked at a high temperature; by later improvements, however, it can now be rolled and modelled into any desired shape as easily as any other metal. Preparatory to rolling the zinc, the ingots which come from the smelter are melted in pots placed in a reverberatory, such as is represented in Figs. 630 and 631. The iron pots, which are very thick, are rapidly attacked by the zinc, an alloy of the two metals being formed, which is considerably less fusible than the zinc alone, and therefore adheres to the sides of the melting pot. Besides being less fusible than zinc, it is considerably harder and more brittle, and hence, when a small quantity of it gets diffused through the metal in the casting of the plates, those portions do not laminate under the rollers, but break, and thus a hole is produced. All the fusible metal is first cast into moderately thick rectangular plates, which are passed under rollers of the ordinary kind as they cool. During the lamination it is necessary to heat the metal from time to time to a temperature ranging between 270° and 300°, passing it, after each heating, under the rollers. By repetitions of these operations, and keeping the metal as near 212° as possible, the sheets may be reduced to any degree of thinness. Sheets of zinc, manufactured in this way, are in very extensive use for roofing, and generally for applications requiring much exposure to the influence of the air. The metal is also formed

into water-tanks, baths, spouts, pipes, *et cetera*, and is much used for covering or *galvanizing* iron, so as to render it less liable to oxidize when exposed to the action of the air. It is valuable for the positive plates in galvanic apparatus, for the engraver in the department known as zincography, and latterly it has been advantageously applied in the separation of silver from its alloys with lead.

ALLOYS OF ZINC.—The principal alloys of zinc are those which it forms with copper, iron, and tin. Those with copper, the reader will find described under *Brass*, in the article COPPER, and the others will be briefly described here. With iron zinc forms a hard, brittle alloy, at a moderately low temperature, but in proportion as the amount of one or other of the metals is increased, these qualities disappear, and the zinc retains its ductility, or the iron seems to acquire greater tenacity. The ductile state is exemplified in the ordinary zinc of commerce, which retains a quantity of iron, sometimes from one to two per cent., and the second or tenacious state is well illustrated by the experiments of NASMYTH upon galvanized iron, the results of which showed that this alloy welds well, and is not only fully as ductile as the best iron, but acquires greater strength or tenacity.

The experiments were made with some zinced wire rope, which was worked up and welded into a bar. It was observed that, although the iron wire was quite covered with the zinc, the portion of the latter metal which was retained at the welding temperature of the iron, or even the portion of oxide of zinc produced, offered no impediment to the welding. The metallic bar produced was remarkably tough, silvery-grained, and withstood punching, twisting, splitting, and binding, in a manner which showed that the iron was not only excellent, but actually improved in quality in a considerable degree. Another trial was made by welding a pile of clippings of zinced iron plates, as in the preceding experiment. The presence of the zinc seemed to offer no impediment to the welding of the iron, and the bar produced presented, on being fractured, a beautiful silvery grain, as good, if not superior, in aspect to the finest samples of *low-moor*, or *bowling* iron. Bars or *blooms* of the alloyed iron, rolled into rods and tested in the cable-proving machine, indicated from five to ten per cent. more strength than the best samples of wrought-iron; thus evidently showing that, so far from being injurious, a small amount of zinc alloyed with iron has the contrary effect. Bars of iron, prepared according to the last-mentioned process, were heated to the temperature of welding, as when converting them into sheathing in the usual manner, on drawing them from the fire, a handful of zinc filings was thrown on the welding surface, and the welding proceeded with. In this severe test no apparent impediment to the process resulted, the iron welding as well as if no zinc were present. Judging from the appearance of the metal welded up from the zinc-covered iron scraps, not only as respects its clear silvery aspect, but as to the increase of strength which it exhibited under proof, it may not be unreasonable to infer that some important improvement might be made in the manufacture of iron by the actual introduction of metallic zinc in some one or other of the

stages of its production; as, for instance, in the puddling furnace. What may be the nature of the action of the zinc has not yet been defined, but the foregoing experiments prove that, so far from being prejudicial to the quality of iron, the zinc appears to have rather an improving effect, and that to such an extent as to lead to the hope that some of the intelligent iron manufacturers may give the inquiry attention, so as to prove by experiment in the puddling furnace, or at any other stage of the process, whether the benefits above mentioned can be realized on a large scale. It may be stated, as a curious corroborative fact, that the strongest cast-iron made in Belgium, and selected for the manufacture of guns, is made from an iron ore in which a compound of zinc forms a considerable portion. Whether the superiority of this iron is due to the presence of zinc, is a question; but the results above detailed would tend to lead to the supposition that such may be the case.—*Ure*.

The results of NASMYTH, recorded above, are opposed to those of GEHLEN, who states that when cuttings of zinc and iron are ignited together, part of the zinc evaporates, while the rest penetrates the iron and makes it denser and very brittle. Doubtless the difference in the results must be attributed to the relative proportions of the respective metals in the alloy. The hard, brittle compound of zinc and iron produced in the pots where zinc has been melted for a long time, or in which the zining of iron plates has been effected, was examined by BERTHIER, who describes it as a bright crystalline body, having a mammillated texture, and composed of concentric layers, very hard and brittle, and less fusible than pure zinc. It dissolves readily in dilute nitric acid, and leaves a micaceous residue of a non-metallic nature, which he terms pure plumbagine, produced, doubtless, either from the carbon employed in the reduction of the zinc ores, or from the cast-iron of the pot. Its density was 6·7, and its composition—

	Centesimally,

Galvanized Iron.—The composition which forms such an extensive article of commerce and general application in the construction of corrugated roofing, and, in fact, entire buildings, spoutings, ships' sheathing, buckets, and various articles in household use, consists of iron plates coated with zinc, and sold under the above inappropriate title. Iron, though possessing so many admirable qualities, such great tenacity, infusibility, and the very important one of welding, is, unfortunately, rapidly acted upon by air, moisture, and dilute acids, to such an extent as greatly to impair its utility. It possesses the property, however, of combining with other metals, and hence it can be readily coated with such; but those metals which possess the persistent qualities that iron wants, are too dear, and therefore their general application is opposed by the great expense which their use would involve the manufacturer and consumer. Coated iron is familiar to most

people in the form of tinned iron plates, or *sheet tin*; but even this material would be too expensive for many of the applications in which iron might be employed with advantage could its oxidizing tendency be overcome. Zinc offers a cheaper substitute, and of late years the production and application of galvanized iron is on the increase. Although MELOUIN discovered the method of preparing zined or *white iron* so early as 1742, still its application did not receive much attention, till of late years SOREL drew attention to the manufacture; but MELOUIN's directions, with slight modifications, are followed even at present in the manufacture of this article. The iron to be covered is deprived of its coating of oxide by an acid bath, composed of sulphuric acid and water, or of hydrochloric acid, or a mixture of equal volumes of the two acids and water, in which it is immersed for a short time; it is then scrubbed with sand or emery powder until the surface is cleaned; after which it is immersed in a concentrated solution of chloride of ammonium, taken out, and subsequently introduced into a bath of melted zinc, covered with fatty matter, or colophony, to prevent oxidation, and stirred in it till the zinc forms an alloy at its surface. The coated metal is then, in some instances, introduced into a second bath consisting of melted tin, such as is used for tinning thin sheet-iron, when a slight coating of tin is formed on the exterior of the plate or bar. Of late years this second bath is generally dispensed with, a few pounds of tin being added to the zinc bath to produce the same effect.

According to MALLET's specification, the plates or bars are immersed in a cleansing bath, composed of equal parts of sulphuric acid, hydrochloric acid, and water in a warm state. After immersion the scales are detached by hammering and scrubbing the plates with emery and sand, and a thoroughly clean surface produced. It is now to be immersed in the preparing bath, composed of a saturated solution of chloride of zinc and sulphate of ammonia; after which it is transferred to a bath formed of six parts and a half of zinc and one of mercury, heated to the melting point of the former metal; in addition to which the patentee directs the addition of one pound of potassium or sodium to every ton of the preceding amalgam. When the immersed iron has attained the temperature of the bath, namely, 680°, it is withdrawn, and is found coated with a metallic layer, of which zinc forms the principal constituent. The affinity of the above alloy for iron is so great that it entirely disintegrates the iron plates, or other articles of this metal when they are thin, or possess but little body; and to guard against this inconvenience, the patentee suggests that some wrought-iron should be allowed to dissolve in the triple alloy previous to the introduction of small articles, such as wire, nails, light chains, and similar objects for galvanizing. Another means of coating iron with zinc is by electricity, and the use of a bath formed by the solution of freshly precipitated oxide of zinc in a saturated aqueous solution of sulphurous acid, or of that of the double chloride of zinc and ammonium. A moderately dilute bath and a weak current answer best. This method is not advantageous in a manufacturing sense,

the simpler mode of immersion being more expeditious and less costly.

Though iron coated with zinc is unquestionably better calculated to resist atmospheric influences without rusting than when it is without such covering, still zincing it is very far from being a uniformly successful protection against its oxidation, and in some cases it increases rather than diminishes this tendency of the iron. Professor CALLAN proposed an alloy of lead and antimony as a substitute for the zinc; but though the disadvantage experienced in many instances as resulting from the employment of zinc are certainly diminished by the use of the alloy, still the cost of the latter precludes its adoption.

Applications of Zinc.—Besides its long-practised application in the production of brass and other alloys, such as German silver, tutenag, *et cetera*, which the reader will find described under COPPER, zinc has been employed extensively in the form of sheets for the manufacture of baths, water tanks, buckets, pails, roofing, spouts, pipes; as a cheap and more durable substitute for sheet and japanned iron, such as architectural ornaments, street lamps; and for making nails, bolts, wire for preserving iron, applied in the form of wire plates to the numerous uses which are everywhere to be witnessed; as a substitute for bronze in statuary, for which purpose it has been found, irrespective of its color, to answer exceedingly well. It is also extensively employed for the positive plates of electrical batteries, for engraving music, in anastatic printing, and numerous other forms, alone and compounded with other metals. In its oxidized and salified state it has another extensive field of application, both in the industrial arts and in medicine, as will be noticed afterwards.

Assay of Zinc Ores.—The estimation of the amount of zinc in any of its ores by the dry method of analysis, is exceedingly difficult. As, however, the metallurgist may desire to have an approximation of the quantity of metal which he can probably extract from any ore, the following brief statement of the operation is submitted here, reserving fuller instructions for the analysis of zincous bodies in general for the end of the article.

BERTHIER, who has made numerous experiments on the subject of the assay of zinc ores, divides the latter into four classes, for each of which a particular method must be pursued. These are, firstly, ores in which the zinc exists as *oxide*, or *carbonate of the oxide*; secondly, those in which the zinc exists wholly or in part as *silicate of the oxide*; thirdly, ores in which the zinc is entirely or in part in the form of *sulphide*; and fourthly, *alloys of zinc*.

To reduce ores of the first class, it is only requisite to mix them intimately with charcoal, and expose the assay for a sufficient time to a white heat in an earthen retort, having a long neck kept sufficiently cool to condense the metallic vapors that are expelled by the heat from the reducing mass. Care must be taken that no air be admitted into the retort, for this would induce the combustion of the metal while in a state of vapor; its neck should therefore terminate in a small opening, or an adaptor of glass drawn to a point be fixed to it

by luting. During the reduction the following simple interchange takes place:—

Even when the reduction is thoroughly effected, it is most difficult to detach the incrustation of metal sufficiently complete for accurate determination. To facilitate this the neck of the retort is coated interiorly with plumbago to diminish the adhesion of the distilled zinc to the body of the apparatus. When all the metal is reduced and driven over, the assayer is often necessitated to break off the neck of the retort to enable him to collect the metal, and not unfrequently to dissolve the adhering particles with nitric acid, and evaporate and calcine the residue, adding the four-fifths of its weight to that of the metal already estimated.

Another process by which the estimation of the zinc may be indirectly made is given as follows:—A certain portion of flux is added to the weighed ore, submitted to the test, and the whole heated at the temperature at which the assaying of iron is usually conducted in a lined crucible. The button of slag containing granules of iron resulting from the ferruginous matter in the ore, is weighed, then ground in a mortar, and the iron, separated by a magnet, likewise weighed. After deducting the iron thus estimated from the total weight of the button of fluxed matter, the remainder is added to the oxide of iron, corresponding to the amount of this metal found as above. The combined weight, deducted from that of the dry ore and flux, leaves a difference corresponding to the zinc expelled during the assaying in the fire. Again, if the quantity of the fixed flux employed be taken from the weight of the button of slag obtained minus the iron, the difference will show the silicious, earthy, and other unreducible matters associated with the zinc.

In the examination of ores of the second class, charcoal alone is insufficient to effect the decomposition, and therefore a flux is employed which, by combining with the silicious matter, liberates the oxide of zinc, and renders it subject to reduction by the carbonaceous matter. Lime or magnesia are the agents usually adopted.

When ores of the third class are under examination, the weighed sample is roasted, to convert the whole of the sulphur into sulphuric acid and partly expel it by the heat; after which the reduction is effected in the same way as directed for the determination of the metal in the first class of ores.

Alloys of zinc with fixed metals, or the compounds of the fourth class, are examined by adding a determined weight of fixed flux, mixed with some charcoal, and heating in a lined crucible at the temperature of the iron assay; all the zinc is volatilized, and from the loss of weight so sustained the amount of zinc is estimated approximatively. If the alloyed metal be of a volatile nature, this course will not afford true results, and the estimation of the constituents of the compound must be effected by the humid assay, which indeed is the most trustworthy, and in the end the most expeditious for the analysis of all zincous compounds.

COMPOUNDS OF ZINC.—Zinc is capable of uniting with almost the whole of the metalloids and salt radicals, producing compounds, which in all instances are of great importance in the arts, and have consequently a very extended application. Its oxygen salts, like those of magnesia, have the property of forming saline compounds with other substances, the importance of which is entirely confined to the department of scientific chemistry connected with stoichiometry. Another remarkable behavior of zinc is, that it readily combines with several organic radicals, such as ethyl, methyl, and radicals of the alcoholic series of compounds, as shown by the very scientific researches of FRANKLAND and others. Several of the combinations of this metal are employed in medicine; and, by a remarkable coincidence, these so employed are most useful in many industrial applications. It will be sufficient to describe here the oxide, the carbonate, sulphate, acetate, and chloride of this metal.

OXIDE OF ZINC.—This compound has various designations, most of them given by the alchemists. Its ancient synonyms were *nihil album*, *lana philosophica*, *flowers of zinc*, *pompholyx*, and occasionally it is still known as *flowers of zinc* or *flores zinci*. When submitted under certain circumstances to the influence of air and moisture, zinc is acted upon in various ways, all of which result in producing the oxide, or a compound from which the oxide can be readily prepared. Thus, when the metal is heated to redness in a free current of air, it burns with a brilliant bluish-green flame producing oxide of zinc. Again, if the zinc be exposed to air and moisture, it is transformed into the same compound; or if carbonic acid should be present, into a basic carbonate of the oxide. In these cases, simple and direct oxidation takes place, the oxide combining, in the latter instance, with a certain amount of carbonic acid. This is the nature of the change which is produced on the surface of zinc exposed to the air, as in roofings, *et cetera*, and which conduces so much to its preservation. It is illustrated by the following equation:—

When zinc is dissolved in sulphuric or nitric acid, the oxide is freely formed, though only in the proportion requisite to produce a salt with the acid employed. In this state it exists in the salified state, but on abstracting the acid by interposing a stronger base, such as soda, the hydrated oxide falls, thus—

The same change takes place when the solution of zinc in hydrochloric acid is acted on, although the oxide does not pre-exist in the menstruum, for at the period of the removal of the radical of the salt the oxygen of the precipitant is assimilated by the zinc, as shown in the equation—

Oxide of zinc is prepared either by the ignition of the metal in a current of air, or by its solution in acids and subsequent precipitation by any convenient agent. If pure oxide be required, the first method will not yield it unless the metal be free from all extraneous metalliferous

matters, which is never the case with the commercial article. In the second method the impurities existing in the zinc can be removed previous to the precipitation of the oxide, and consequently this method is preferred when it is important that no foreign matter should exist in the preparation.

In operating by the first method, a hessian crucible is filled with zinc to one-eighth its capacity, and then placed in a wind furnace so inclined that the lower part rests upon its edge on a piece of tile at the bottom, whilst the upper part is supported by the rim of the furnace. The fire is then urged till the crucible and contents attain a strong red or white heat. At this period a scum of oxide appears on the metal, and must be removed with an iron spatula as fast as formed, till the combustion of the zinc is completed, when a fresh charge may be introduced. The oxide as collected is placed upon an iron plate to cool, and is afterwards rubbed up with water to the consistence of a thin pasty mass, which is next diluted largely, allowed to settle for a few minutes and then decanted, more liquid being agitated again with the subsided matter, and treated, after a minute or two's repose, in the same manner. By continuing the treatment so long as the decanted liquors flow off milky, all the oxide is separated from the metallic matter which escaped ignition in the crucible, and which may be introduced with another portion of zinc to undergo fresh combustion. All the decanted liquors are collected together and allowed to subside perfectly, when the clear water is poured off, the deposit thrown upon a cloth filter to drain, and finally it is dried at a gentle heat. The yield of zinc oxide obtained in this way, when the whole of the metal is burned, will be somewhat more than the weight of the zinc employed.

When the oxide is to be prepared by the liquid process, rectified sulphuric acid, diluted with ten times its weight of water, is poured upon the zinc previously rolled into thin sheets, or granulated by pouring it whilst in a molten state into a vessel of water, employing an excess of the metal with the view of causing the foreign matters, such as lead, tin, cadmium, bismuth, arsenic, *et cetera*, to be precipitated; or a solution of crystallized sulphate of zinc in thirty parts of water may be taken, immersing in it for forty-eight hours a few thin plates of zinc, which act in the removal of any foreign bodies in the same way as the excess of metal in the foregoing method. The clear solution is decanted in either case, or strained, if necessary, and a hot concentrated solution of carbonate of soda is added to it as long as a precipitate forms. This precipitate, which settles much more readily when thrown down from hot solutions than from cold ones, is now washed with hot distilled water by decantation, till no further trace of sulphuric acid is detected in the washings with a solution of chloride of barium. After thorough washing it is collected on a cloth filter, allowed to drain, pressed and dried, and finally heated to redness in a hessian crucible, till the whole of the carbonic acid is expelled, as evidenced by its not effervescing on the addition of dilute acid.

Properties.—Oxide of zinc is a white, tasteless, inodorous powder, which at red heat acquires a yellow

color, that vanishes on cooling. When subjected to a higher heat it melts into a yellow glass, and at a sustained white heat volatilizes. It is insoluble in water, but readily soluble in acids, giving rise to the corresponding zinc salts. When freshly precipitated, oxide of zinc is readily soluble in alkaline solutions, as also in concentrated ones of sesquicarbonate of ammonia, producing compounds in which it assumes the characters of a salt radical that are called *zincates*. Heated with charcoal it is readily reduced to the metallic state.

Uses.—Oxide of zinc is employed principally in medicine. Latterly, however, it has been successfully introduced as a substitute for carbonate of lead—white lead—in the manufacture of paint; and to meet this extended use several processes have been devised for its preparation, to which reference will be made presently. The oxide has been prescribed in some cases of epilepsy, chorea, hysteria, catalepsy, and whooping-cough, as well as in some painful affections of neuralgia and gastrodynia, with occasionally good effect, though its frequent failure has shaken the confidence of practitioners in its efficacy. It has been found serviceable in five-grain doses, combined with extract of henbane or hemlock, in colliquative perspiration. It is useful as a desiccant to allay or prevent excoriation in children, as well as in cases of chronic skin diseases, attended with profuse secretion, and also in other ailments of a similar nature. In large doses, oxide of zinc acts as a slight irritant and causes vomiting, and by long-continued use it acts as a slow poison.

Oxide of zinc is composed of—

	Atomic weight.	Centesimally.
1 Eq. of zinc,	32.0	80.0
1 Eq. of oxygen,	8.0	20.0
	40.0	100.0

Its chemical symbol is ZnO.

CHLORIDE OF ZINC—*Muriate of zinc; butter of zinc.*

—This compound of zinc has long been known and applied in medicine. It is prepared by adding hydrochloric acid of specific gravity 1.130 to granulated zinc portionwise, and applying heat till the latter is dissolved. Four parts and a half of acid are required for every part by weight of metal for its perfect solution. A few fragments or thin plates of zinc are introduced into the solution, and set aside for twenty-four hours, during which time any lead, tin, antimony, cadmium, or other metals of this class that may be present in the liquid, are precipitated; after this, the clear liquid is separated by filtration from the deposit that may have formed, and about one-sixteenth of its bulk precipitated, with a very slight excess of carbonate of soda, the basic carbonate separated and well washed while on the filter, and then introduced into the remainder of the liquid. Chlorine, generated in the usual way from binoxide of manganese and hydrochloric acid, is now passed into the menstruum till it smells of the gas. A further period of twenty-four hours is given to the liquid to stand, and if, after this period, a portion of the clear solution exhibits any indication of the presence of iron, either by giving a bluish-black color with tincture of galls, or by striking a deep blue with ferricyanide of potassium—red prussiate. A further

portion of the liquid is taken and precipitated with carbonate of soda, as above, and the mass so obtained, after thorough washing, is added to the liquor containing the zinc, allowed to digest for a further period, and afterwards tested for the presence of iron in the manner indicated. If necessary, the process is to be repeated a third and a fourth time, or until the whole of the iron is separated in the form of sesquioxide; but it rarely happens that this metal remains after the second digestion. After filtering from the formed deposit, the liquid is evaporated in a porcelain or hard stoneware dish on the sand-bath, taking care, as it becomes denser, to keep the contents of the vessel constantly stirred, till the whole of the water is expelled. Chloride of zinc remains, and should be transferred, whilst still hot, to well covered vessels for use. When it is necessary to deprive it of the whole of the water, the residue from the evaporation should be introduced into a glass vessel with a narrow neck, and heated at a higher degree, till the chloride of zinc begins to distil, at which period the fused matter is poured out on a slab, and when cooled broken into fragments, and preserved in well-stopped bottles.

In the preceding process the action of the acid is simple and well understood, its chlorine uniting with the metal, while its hydrogen is disengaged, thus—

The action of the chlorine is to convert the iron, which always exists in commercial zinc, from the state of protochloride to which the hydrochloric acid reduces it, to that of sesquichloride, as shown in the equation—

with the view of precipitating it subsequently with the basic carbonate of zinc—3 (ZnO, HO) 2 (ZnO, CO₂)—produced by the carbonate of soda in the portion of the liquid submitted to its action. The manner in which its separation is chemically effected may be represented thus—

that is, three equivalents of the basic carbonate convert five of the iron salt into five equivalents of insoluble sesquioxide, being themselves reconverted into fifteen equivalents of the chloride of zinc by the assimilation of the chlorine from the iron compound.

Chloride of zinc may be prepared by other processes, such as heating equivalent weights of oxide of zinc and chloride of ammonium, or by distilling a mixture of dry sulphate of zinc and chloride of sodium in a retort, the substances being employed in the ratio of their equivalent weights. In either case chloride of zinc results, the change in the former being $\text{NH}_4 \text{ Cl} + \text{ZnO} = \text{NH}_4 \text{ O} + \text{Zn Cl}$; and, in the latter, $\text{ZnO, SO}_3 + \text{Na Cl} = \text{Zn Cl} + \text{NaO, SO}_3$. The salt in the first formula remains after the expulsion of the ammonia; but in the second instance it distils over, leaving the

sulphate of soda in the retort. Preference is, however, generally given to the method of preparation by solution.

Properties.—Chloride of zinc, deprived by fusion of all moisture, is a whitish-grey, semitransparent soft mass, like wax, that melts at a temperature below redness, and at a higher degree of heat sublimes, being at the same time partially decomposed into a basic chloride of zinc and an acid salt, which collects in crystalline needles in the receiver, and oxide of zinc retaining a little of the chloride that remains in the retort. Exposed to the air, the salt rapidly attracts moisture and deliquesces. It has a burning, nauseous, saline taste, even in highly dilute solutions. Alcohol and ether readily dissolve it, the solutions manifesting an acid reaction. It unites with chloride of ammonium and chloride of potassium, and forms definite compounds with them, likewise with albumen and gelatin, producing difficultly soluble precipitates. The alkalies and alkaline carbonates decompose it, giving rise to precipitates of oxide and basic carbonate of zinc, according to the agent used, but which precipitates, as stated under *Oxide of Zinc*, are soluble in an excess of many of these reagents, owing to zincates of those bases being formed. Sulphuric acid readily converts the chloride into a sulphate of zinc, with evolution of hydrochloric acid. The pure salt has a composition corresponding to the symbol Zn Cl , being composed of—

	Atomic weight.		Centesimally.
1 Eq. of zinc,.....	32.0	47.407
1 Eq. of chlorine,.....	35.5	52.593
	67.5	100.000

The composition of the hydrated salt is Zn Cl, HO ; it is crystalline, and contains, according to SCHINDLER, in one hundred parts—

		Centesimally.		Schindler.
Zinc,.....	32.0	=	41.83 39.80
Chlorine,....	35.5	=	46.40 43.81
Water,.....	9.0	=	11.77 16.39
	76.5		100.00	100.00

Uses.—Owing to its physiological effects, the chief use of chloride of zinc is in medicine; but latterly it has been successfully introduced as a disinfectant, and likewise for impregnating wood in order to preserve it from decay or putrefaction. Its use has been much extended in the first application by its qualities as a caustic or escharotic, destroying the life of the part with which it comes in contact, owing to its combination with the albumen and fibrin of the tissue, which substances appear in the form of an eschar some time after. Many prefer chloride of zinc in this capacity to nitrate of silver, and even to chloride of antimony, as it penetrates further, and leaves the wound or sore in a more healthy state after the removal of the eschar. When taken into the system, chloride of zinc acts, in large doses, as an irritant or caustic poison, and affects the nervous system. It produces a burning sensation in the stomach, nausea, vomiting, anxiety, short breathing, cold sweats, fainting, and convulsions. In very small doses, none of these effects are attendant upon its use.

Sir WILLIAM BURNETT introduced a concentrated

solution of this compound some years ago, as a disinfecting and antiseptic fluid. The liquid contained about one-fourth of its weight of the salt, and had a specific gravity of 2.0. Its antiseptic qualities depend upon its power of uniting with animal tissues, and forming permanent bodies with them; and hence its use in preserving anatomical subjects for dissection; its disinfecting quality arises from its power of decomposing sulphide of ammonium and sulphide of hydrogen to some extent. It is inferior, however, in this respect to a solution of chloroxide of calcium—bleaching powder—and several other combinations, as stated under *Disinfectants*—owing to the latter being not only capable of arresting gaseous emanations, but also of disseminating a disinfecting gas into the air which arrests any foul odor immediately.

SULPHATE OF ZINC—*Zinc vitriol*; *white vitriol*.—This salt, which is said to have been known at the end of the thirteenth century, has been long manufactured on a large scale at Goslar in Germany. It was long erroneously considered as a modified sulphate of iron, but this notion was abandoned when the true metallic nature of zinc became known. It is much more important than any other saline combinations of the metal, as well for its cheapness as for being the means of preparing the other compounds of zinc, and likewise for the extended uses to which it is applied in the arts and in medicine.

Preparation.—At Goslar, where sulphate of zinc was first extensively manufactured, as well for the preparation of Nordhausen vitriol as for application in the medicinal art, the following process was adopted:—

The natural deposit of ore, consisting of sulphates of zinc, lead, copper, silver, and iron, was assorted to obtain the portions richer in zinc; these were submitted to a roasting operation in heaps, during which the sulphur was converted into sulphuric acid, and by this the metals were changed into the corresponding sulphates; the mass was then lixiviated, and the soluble salts, consisting of sulphates of zinc, iron, cadmium, copper, and silver, washed out, and afterwards evaporated till the sulphates crystallized. The impure salt, after slight washing, was heated to the melting point, and the whole, or chief, part of its water of crystallization expelled. On allowing the mass to cool at this stage, it formed a white opaque granulated substance resembling sugar. At a later period this product was freed from portions of its impurities by re-solution in water, and introducing into the lie fragments or plates of zinc, which were allowed to remain in contact with it for a longer or shorter time. After drawing off the clear liquid, it was evaporated, and the zinc salt crystallized out as before. This method is still practised, not only at Goslar, but in several other localities where blende is abundant.

Sulphate of zinc is obtained at present as a secondary product from the acid liquors of galvanic batteries employed in developing electricity, as also from the liquors remaining after the precipitation of copper on the large scale from its solutions, by metallic zinc.

The pure salt may be obtained by treating commercial, or purified zinc, in a divided or granulated state, with sulphuric acid diluted with fifteen times its weight

of water, in a leaden vessel, using the acid while still warm; three parts of rectified acid of specific gravity 1·84, are required to convert two parts of the metal into a sulphate. The mixture is sustained at a gentle heat in order to promote the solution, and with the same view the contents of the vessel are agitated occasionally. After the solution is effected, a quantity of metal, about one-eighth of the portion dissolved, is introduced into the liquid, and left to repose during thirty to forty-eight hours, the slight heat being still maintained. By this treatment the lead and other less oxidizable metals are precipitated, and are separated by filtering the liquid while still hot. The filtrate is now largely diluted with water, and a portion of it taken, precipitated with carbonate of soda, as stated under the preparation of chloride of zinc, filtered, washed, and added to the remainder of the solution of the sulphate. Chlorine is then transmitted into the mixture till the protosalt of iron present in it is converted to a sesquisalt; after which the whole is allowed to stand till the iron falls in the form of sesquioxide. The various changes by which the purification of the salt is effected in this instance, are analogous to those specified under *Chloride of Zinc*, and therefore need not be detailed. After filtering the liquid from the deposit of sesquioxide of iron, it is evaporated till a pellicle begins to form on the surface, when it is permitted to rest to allow the salt to crystallize. A second crystallization removes all traces of impurities, but this is rarely required.

Properties.—Sulphate of zinc crystallizes in colorless, transparent, right rhombic prisms, containing seven equivalents of water of crystallization. In this state it is very soluble in water, requiring somewhat less than its weight of cold, and considerably less than its weight of the boiling liquid; thus, according to KARSTEN, one thousand parts of water at 63·6°, dissolve nine hundred and twenty-three parts of this salt, forming a solution, the specific gravity of which is 1·4353. DUMAS states that one hundred parts of water, at the ordinary temperature, take up one hundred and forty parts of the sulphate; while other authorities assert that not less than two and one-third parts of water are necessary for the liquefaction of one of the salts, which is evidently erroneous. Boiling water takes up a much larger quantity of the salt, and even alcohol dissolves traces of it. Sulphate of zinc, according to the circumstances under which it is prepared, is found associated with different quantities of water of crystallization, varying from one to seven equivalents; but the compound crystallizing from its solutions at temperatures below 80° to 86°, always assimilates seven equivalents of water. This salt effloresces slightly in the air; exposed to a heat of 212° it loses 37·3 per cent. of moisture, or six equivalents, the last equivalent being obstinately retained till the heat rises to 451°. By the sudden application of a high temperature the compound at first fuses, and after the expulsion of the contained water, decomposition of the salt follows; anhydrous sulphuric acid, sulphurous acid, and oxygen being eliminated, while a highly basic salt remains. On continuing the heat, however, till it approaches to whiteness, only pure oxide of zinc is left. Heated with charcoal at a red

heat, it is reduced to the form of sulphide; but at a sustained white heat, the metal is isolated and volatilized in the form of vapor. Anhydrous sulphate of zinc, on being exposed to moist air, readily assimilates its full complement of water of crystallization with reagents. It affords the usual reactions of oxide of zinc in a salified state, and is capable of forming numerous double salts with other bodies. Sulphate of zinc, in its crystallized form, is represented by the formula $\text{ZnO}, \text{SO}_3, 7 \text{HO}$, and is composed of—

	Atomic weight.	Centesimally.
1 Eq. of oxide of zinc,	40·0	= 27·972
1 Eq. of sulphuric acid,	40·0	= 27·972
7 Eqs. of water,	63·0	= 45·056
	143·0	100·000

Uses.—This salt, is used in medicine, in consequence of its physiological effects, which are, when administered in small doses, of an astringent, antispasmodic, and tonic nature; whilst taken in large quantities it is poisonous, causing vomiting, purging, coldness of the extremities, and a fluttering pulse. In full doses it acts as a safe emetic, but care should be taken that it be thrown off the stomach, for if retained for any length of time it occasions nausea and prolonged retching. In this capacity of emetic it is of great use where poisoning is suspected, as it acts rapidly. Sulphate of zinc is frequently used, owing to its astringent and caustic properties, in diseases of the eyes, and generally with good effect. In some cases it is used by dyers as a mordant; also as an *oil drier* for painting.

CARBONATE OF ZINC.—The preparation of the neutral carbonate of oxide of zinc is somewhat difficult, owing to the feeble affinity of the oxide for carbonic acid. If, however, the precipitate which occurs on adding a solution of bicarbonate of soda or of potassa to a solution of zinc be, after washing, disseminated in water, and carbonic acid charged into the liquor, the precipitate is dissolved in the form of a bicarbonate, and on evaporating the liquid in an atmosphere of carbonic acid, the neutral or monocarbonate of oxide of zinc is obtained. Its formula is ZnO, CO_2 .

The ordinary carbonate of this oxide is a basic compound, containing five equivalents of base to two of acid. It is obtained by adding a solution of carbonate of soda to one of sulphate of zinc, taking care that the latter is in slight excess. The change which succeeds may be exemplified thus—

When the precipitant is in excess, a portion of it combines with the basic salt and cannot be removed by washing. For this reason carbonate of ammonia is sometimes preferred, only an equivalent quantity being employed, so that excess of the salt, which would dissolve a part of the zinc carbonate, is avoided. The precipitate in either case is washed well and dried at 212°.

Properties.—It is a loose white powder resembling the carbonate of magnesia of the shops, almost insoluble in water, easily soluble in acids with evolution of carbonic

acid, and converted by a red heat into oxide of zinc. Like the oxide it is readily reduced by carbon at a red heat. MOORE asserts that several of the varieties sold in the shops as calamine or carbonate of zinc contain no zinc whatever, but mixtures of carbonate of lime, sesquioxide of iron, and sulphate of baryta. When a sample of the zinc carbonate is suspected to be fictitious, its purity is readily ascertained by dissolving it in dilute hydrochloric acid, and adding an excess of carbonate of ammonia to the liquor. It should be wholly soluble in the acid, and the precipitate at first formed in the second case should be dissolved by the excess of the ammoniacal salt. A residue on the one hand, or a persistent precipitate on the other, indicates adulteration.

Uses.—Physiologically the carbonate of zinc has the same properties as the oxide, and is applied medicinally in like cases. In the arts, this compound has of late years, together with the oxide, acquired some importance as a substitute for white lead in painting.

ACETATE OF ZINC.—The reader will find this salt described in Vol. I. page 48. It may be stated here, however, that it can be conveniently prepared from the carbonate of this base and acetic acid. Two parts of the carbonate are heated with successive portions of acetic acid of specific gravity 1.045—containing sixty-four per cent. of water—till complete solution is effected. About five parts of acid are required. The solution is filtered while warm, and set aside to cool for a day or two, after which period it is decanted and concentrated to the crystallizing point, when, on cooling, the acetate will deposit. Acetate of zinc possesses a slight odor of acetic acid and a bitter saline nauseous taste. On being heated it fuses with the loss of water, and at length blackens, giving off the usual empyreumatic products resulting from the igneous decomposition of the acetates; and if the temperature be very elevated, the oxide of zinc will be likewise reduced.

Acetate of zinc is soluble in three parts of cold and in half a part of boiling water; in thirty parts of alcohol of eighty per cent. at the normal temperature, and in one part at the boiling point. The solutions have an acid reaction.

Uses.—Physiologically considered, the acetate of zinc is reputed to have the same properties as the sulphate, but some French writers deny that it has a poisonous effect even when administered in large doses. The salt is used by dyers as a mordant.

ZINC-WHITE.—This pigment, to which considerable attention has been given of late years, is either the anhydrous oxide, the hydrate oxide, or hydrated basic carbonate of zinc. Its whiteness is equal to that of white lead, and not being tarnished like the latter by sulphurous vapors, it has been proposed to introduce it as a substitute for white lead in painting, especially as it affords a more permanent color, is cheaper, and does not involve the great risk and sacrifice of life which, however carefully the preparation of the carbonate of lead may be conducted, is occasioned among the workers engaged in that manufacture. The principal objection to its general adoption is, that the paint compounded with it is less drying than those in which lead constitutes the basis, and also that it does not cover or spread so

perfectly as white lead; or, in the language of the painter, that it does not possess sufficient *body*. With regard to its non-drying qualities, improvements have been suggested which, if acted upon, would, in a great degree, obviate this objection; and as to the want of body, the painter can well afford to spread a thicker layer of the zinc-white, seeing that a given weight of the latter is considerably more bulky than the same quantity of the former, in consequence of the lesser density of zinc, as well as its much lower atomic weight, which is to that of lead in the proportion of thirty-two to one hundred and four.

GUYTON DE MORVEAU was the first to propose the substitution of oxide of zinc for the basic carbonate of lead in painting. LASSAIGNE likewise drew attention to the subject about 1821, and has lately communicated the fact that an oil painting finished at that time with oxide of zinc has hitherto retained its brilliant whiteness. The manufacture of the zinc-white owes much, however, to M. LECLAIRE, who was among the first to establish its manufacture on a large scale for this purpose. More recently several patents have been taken in England for the preparation of the oxide of zinc for the painter's use, and some of these will be referred to further on.

Manufacture.—At first metallic zinc was the material from which the zinc-white was prepared, the simple change effected being merely the dissipation of the metal in the form of vapor. While in this state, and still at a high degree of heat, the introduction of a current of air causes the metallic vapor to ignite, producing oxide of zinc in a finely-divided white powder, which, when collected, forms the substance in question. The arrangement by which this change is effected is shown in Figs. 645 to 646. In Figs. 645 and 646, the retorts from which the zinc is distilled are represented in section and elevation. They are similar to gas retorts, and are depressed cylinders, *a, a*, of refractory clay, such as that of which glass pots are made. Their length is about

Fig. 645.

Fig. 646.

Fig. 647.

twenty-eight inches, their breadth ten inches, and their height about six inches; the walls are two and a

quarter inches in thickness; the aperture, *b*, which serves the double purpose of introducing the pigs of zinc, and allowing the metallic vapors to escape, is four inches in breadth and two in height. Eight or ten of these are placed in a double range, back to back, in a reverberatory, represented in plan and section in Figs. 648, 649,

and 650. The fire is at *c*, the heat and flame of which pass over the cylinders and return beneath the floor of the reverberatory by the flue, *c*, *d*, *f*, *g*, *h*, into the chimney, as seen in Fig. 649. When the interior of the furnace and the retorts are observed at a reddish white heat, one or two bars of zinc are introduced into each of the retorts. The metal soon melts and enters into ebullition, the vapor being disengaged by the aperture, *b*, of each retort, where it comes into contact with a

Fig. 649

current of air heated in the cast-iron pipes, *ss*, to about 570° by the waste caloric of the furnace, and enters into combustion. The metallic oxide so produced is carried along by the current of gas into the pipes, *kk*, which surmount the mouth of the retort, and is deposited in the chambers, *LL*, four of which are in connection with each other by apertures alternately at the lower and upper part of their partition walls. The disposition of the condensing chambers and other parts of the apparatus is shown in Figs. 650 and 651. Here *A* indicates the furnace, *B* the pipes leading to the chambers, the last opening in the outer one of which is covered

with a fine metallic gauze stretched on an iron sash or framework, for the purpose of intercepting all the particles of the zinc-white, whilst the meshes of the

Fig. 650.

wire affords sufficient space for the egress of the nitrogen and other gases into the flue or passage, *G G*, leading to the chimney, *H*. In this conduit two other screens, similar to that above described, may be fixed, but somewhat finer, to prevent the loss of as little as possible of the powder. After a while the wire gauzes become covered with the powder, but before the meshes are closed they are cleaned and replaced.

Fig. 651

The oxide of zinc thus produced is always of good quality, unless indeed an excess of impurities exists in the metal employed. That which is inferior is always deposited in the first chamber, being impregnated with the oxides of the metallic bodies contained in the zinc, and also with a finely-divided powder of the zinc itself, in consequence of some of its vapor being carried over before it underwent combustion. In consequence of these impregnations, the powder collected from the first chamber should always be screened, and the product devoted to the commoner kinds of painting. It is necessary during the formation of the oxide of zinc, to clear the openings communicating with adjacent chambers, lest the deposition of the powder on the walls should accumulate so as to block up the passage. This is done by means of an iron rod passed through the wall, and commanding the opening. After the conversion of the charge is completed, the oxide of zinc deposited in the chambers is removed simply by placing a barrel beneath the mouth of the hopper-shaped opening in the chamber, and drawing the sliding-plate which is used to secure it while working. The zinc-white is then easily scraped into the receiver, and there reduced by pressure to the least possible volume. It is now ready for the market, or for compounding with the oil as in the manufacture of paint. Three furnaces like those described, each furnished with eight retorts,

work off from twenty-eight to thirty hundredweight of zinc in the twenty-four hours. This quantity ought to produce from thirty-five and a half to thirty-seven hundredweight and a half of zinc-white; but in practice the average yield amounts to only thirty-one and a half to thirty-four hundredweight.

Of late years several improved methods have been devised for the preparation of this substance, the most important of which, in the Editor's judgment, will now be briefly stated.

M. LECLAIRE's mode of operation is indicated in the following description and figures, taken and abridged from *Le Génie Industriel*. Figs. 652, 653, and 654 show

Fig. 652.

the distillatory furnace in longitudinal and transverse vertical sections and in plan. In these figures, A represents the fire-door, B the fire, and C the retorts, which are made of refractory material. Five are generally ranged at either side of the grate, but the number can be varied according to circumstances. The volatilized metallic vapors escape by the orifice, D, of the retort, before which are disposed a series of plates, E, called scrapers, attached to a horizontal iron rod, F, by similar pendant ones. By motion communicated by hand or machinery to the horizontal rod, the scrapers, E E, are moved backwards and forwards, and coming at each movement against the door of the retort, any oxide which adheres to the aperture is knocked off. The oxide and metallic vapors issuing from the retort are received in small receptacles, G G, which open into an inclined channel that terminates in another funnel-shaped conduit, G¹, and this leads them into the receiver, G². It is evident that the small conduits, G G, receive only such matters as solidify in the mouth of the retort, and which from their density cannot be drawn off to the receivers by the force of the current of gases passing through this arrangement to the chambers wherein the oxide of zinc is collected. A small plate-iron cage or box, H, is fixed over the mouth of each of the retorts in order to isolate them. It rests upon a framework of metal, H¹, fixed into the wall of the furnace, and so constructed that it may be

removed at will by means of a crane, or by making it slide or roll on a framework or small railway. The anterior aperture is directed towards the orifice of the

Fig. 653.

retort in such a manner that the products of the distillation empty themselves into it, and the posterior part has a door which may be opened at will. A trap-door, J, is contrived in the suspended plate, K, and which can be raised or lowered at will by an iron-wire rope passing through the posterior plate, I, of the box, H, without opening the door in this part of the latter. Sometimes, instead of lifting the trap-door, it is so formed that it can be drawn backwards when it is necessary to open

Fig. 654.

it. K designates the suspended plate upon which the box or cage is placed; it is isolated in its construction from the chamber of oxidation. Currents of cold air may be directed upon this plate in order to cool it, so as to resist the temperature of the chamber. The hot air, admitted for the combustion of the metal, enters from the pipe, L; it communicates with the passage from the retorts to the receivers, and so drives the oxide of zinc formed into the latter. In the receivers the inventor places cloths for sifting or screening the products, the floor of each being a kind of hopper, or inclined plane, whereby the product gliding over the cloth is separated into its various qualities of fineness, and received at once into separate boxes placed beneath

the sifter. In order to retain the finely-divided particles of zinc-white which arise from the agitation, cloths are suspended at regular distances. These, while they afford a passage to the gases, retain the particles of metallic oxide, and so prevent a loss of material.

A draught pipe, Q, draws off the air and gases as well as the finely-divided oxide from the oxidising chamber through the whole arrangement. Another pipe, R, placed at the top of each retort, draws into it by a funnel-shaped opening all vapors and powder emitted from the retorts whilst they are being charged, and the draught of which, whenever it is isolated from the oxidising chamber is sufficient to draw the products through a series of chambers not shown in the drawing, having cloth screens as usual to retain the oxide of zinc. The ventilation of both the draught pipes, Q and R, is effected by means of the waste heat of the furnace.

The same inventor combines the principle of the reverberatory furnace in the distillation of zinc for the purpose of making zinc-white. In this arrangement he so disposes the retorts that the flame from the coal fire circulates round them, and then passes into a chamber over the dome inclosing the retort, where pipes may be laid for raising the temperature of the air which is forced into the space surrounding the mouths of the retorts to oxidise the zinc vapors. The oxide so produced is conducted to receiving chambers in a manner somewhat similar to the two methods already described.

ROCHAZ'S patent, dated in 1849, describes a construction of furnace suited either to the conversion of metallic zinc, or of ores of this metal, into the oxide. In the first case he uses clay crucibles, and arranges them in three rows in a furnace, supporting them by two intermediate fire-brick walls and by the side walls of the furnace, and so securing the crucibles at the surface that no vapors or smoke from the fire can issue from the chamber beneath them, but must pass off through passages in the bearing walls by small flues into the chimney. A loose slab or clay tile is used as a cover for the vessel wherein the distillation is effected, and the whole is inclosed by a flat roofing of refractory tiles, well cemented and raised a few inches above the crucibles, for the introduction of air from without, for oxidising the metallic vapors. This space leads to a large chamber, in which plates of iron are suspended in a slanting direction, so as to cause the current of vapor, loaded with oxide of zinc, to take a sinuous and zigzag course in passing through it. In addition to these he fixes bands of hemp, or other textile material, at intervals transversely in the chamber, with the view of intercepting the last portions of the zinc-white. Further he contrives that the upper end of these bands shall pass through the walls of the chamber and dip into a trough of water, so as more effectually to condense the zincous vapors in the interior. He directs that the chambers more distant from the furnace be constructed of sailcloth, which affords the advantages of being easily accommodated to space, and of keeping the walls cooled by means of a copious sprinkling of water, applied exteriorly, and which causes the oxide of zinc to deposit more readily. The same patentee

claims a method for preparing the oxides from the ores by a previous roasting, and introducing them, thus prepared, with charcoal or slack, into cylindrical or square clay crucibles, somewhat similar to those employed for the reduction of the metal at Vieille Montagne, but without the condensers, opening into a closed channel in the front, through which a current of air is introduced, and which carries the oxide of zinc, resulting from the combustion of the metal, into a chamber disposed similarly to that described; likewise a blast furnace, represented in Fig. 655, for the same purpose. In this figure the mixture of roasted ore and fuel is introduced into the passages, A A, B B; others are filled with

Fig. 655.

coke or other fuel; all of which are covered with tiles, C C; E, the cavity of the furnace, which is always kept filled with fuel from the passages, B, B, and in which the reduction of the ore is effected by means of the blast introduced through the tuyere pipes, H, H, more especially in the region of F. The slags and residue descend into the cavity, G, whilst the vapors of zinc pass off by the channel or flue, D, into the condensing chamber, as soon as the stopper, a, inclosing the mouth of the chamber, E, is removed. In the latter flue they meet a stream of air that effects their oxidation. The chamber is evidently required to be more extensive in this instance, owing to the gaseous products of the combustion of the fuel being carried along with the oxide of zinc produced in the flue, D; but, excepting this inconvenience, the patentee asserts that no other will result, for all the carbonaceous or sooty products, produced in the region of the blast, are entirely reduced or consumed in passing through the column of incandescent fuel above F, so that only pure gases, which are not calculated to discolor the product, are evolved.

KNOWLYS secured a patent in 1850, in which, among other claims, is a method of preparing the zinc-white from its ores, by dissolving the oxide in sulphuric acid, and, after clarifying the solution by filtration or subsidence, precipitating the metallic oxide with a solution of carbonate of soda. The precipitate, after being washed and collected, is then dried by means of heat and pressure, and the compound so produced is either used in this state or reduced by ignition to the oxide and then compounded into paint in the ordinary way.

PROTHEROE employs an ordinary cylindrical retort, having inlets for the passage of a current of air at the

posterior end, and another for raking out the heavy oxide which forms on the surface of the metal and the walls of the retort, the lighter and finer particles being conveyed by a pipe with the current of air to a condensing chamber, which is divided by partition walls of brick, or other material, into several compartments. In each division he disposes two frames or sashes, on which fine wire gauze is stretched for the purpose of intercepting the particles of powder in their course through the several divisions. Metallic zinc is preferred as the substance to operate upon, and a reverberatory furnace is employed to reduce the metal to vapor. The quantity of heavy oxide skimmed off the surface of the metal and from the walls of the retort, is drawn out by a rake into a passage which conducts it to a receiver in an inclosed chamber beneath the level of the sole of the furnace.

In the method patented by SCOTT, a clay retort of the usual form is used, imbedded in sand, potsherds, or pumicestone, and so placed in the furnace that the products of the combustion pass freely round it. The metallic zinc, which is directed to be used, is introduced through an inclined aperture, which is usually closed by the unmelted portion of the block of zinc. The air which oxidises the vapors of zinc issuing at the top of the retort, is admitted to an intermediate chamber, where both meet, and the product is carried by the current through a passage into a depositing chamber, the roof of which is constructed of zinced iron, and is capable of being converted by a raised ledge, into a shallow cistern, for the purpose of cooling the interior. The bottom of the chamber is divided into a number of funnel mouths, which, by attaching cloth or other material to the narrow part, lead the zinc-white at once into casks placed beneath to receive it.

GEYELIN'S patent, sealed in 1853, is based upon the same principles, only the apparatus is slightly modified, and a jet of steam is employed to effect the rapid oxidation of the metallic vapors as they rise from the retort, and also to aid in producing a certain amount of caloric expended in the operation. The jet of steam is introduced at the farther end of the retort, and passing over the metal, it is decomposed, the oxygen combining with the zinc, and the hydrogen passing off to be consumed in the air channel outside the distillatory apparatus.

TITTERTON prepares the zinc-white from the dross and dregs of the purifying pots of the zinc-smelting establishments by heating them alone, or mixed with a certain quantity of coke or charcoal, according to their composition. He employs two condensing chambers, the first intended for retaining oxide of cadmium, or other impurities, and the second for collecting the light white oxide of zinc. This patentee employs pressure, and a subsequent heating process, with the view of obtaining a denser compound, and therefore better suited for painting.

ZINC-WHITE PAINT.—Like white lead, the oxide of zinc requires to be mixed with an oily vehicle, to be applied in painting. As oxide of zinc does not readily form a saponaceous compound with fats or oils like oxide of lead; the paint which is prepared with it and ordinary linseed oil, does not dry or harden for a long time. This peculiarity was at first one of the principal

drawbacks to the more general use of the zinc instead of the lead paint. Another of its defects is said to be its transparency, owing to which a layer of the zinc-white paint does not exhibit so much *body* or opacity as a similar one of white lead. Both these defects, which can be almost entirely overcome, are more than compensated by the permanency of the oxide of zinc as a pigment under all circumstances, and its comparative innocuousness both in the manufacture and the application; whereas the poisonous qualities of white lead constitute a fundamental objection to it. At first, manufacturers of zinc paint were led to the adoption of the practice of boiling the oil with a large quantity of litharge, for the purpose of causing it to be more siccative; but by this method the color of the paint is rendered liable to tarnish on exposure to sulphurous emanations. Instead of litharge, experiments have led to the choice of salts of zinc, such as the chloride and sulphate, a small per centage of which, on being mixed with the oil or oxide, confers upon the paint the property of readily hardening. The same result is obtained by employing an oil dried by boiling it with about five per cent. of peroxide of manganese, or even magnesia has been recommended, and is said to answer quite as well as the manganese; in either case a paint retaining its white color permanently is obtained.

Manufacturers classify the several qualities of the zinc-white into four kinds, namely, *snow white*, *zinc white*, *stone grey*, and *grey oxide*; the first two are employed where a pure unalterable white color is required; the third is used for a ground color for the walls of houses, iron painting, and the like; and the fourth is peculiarly adapted for the painting of ships and wood-work, and likewise for the ground of more expensive colors on stone or cement. Various shades may be given to paint of which zinc-white constitutes the basis, by grinding up with the oil, used as the vehicle, several metallic and other compounds of an unalterable nature in different proportions. Thus, an orange-yellow is obtained by using kermes—sulphide of antimony; a citron-yellow by employing chromate of zinc; a green by adding a mixture of chromate of zinc and a few per cents. of cobalt blue. In like manner oxides of iron and of manganese, ultramarine, lampblack, *et cetera*, communicate tints to the paint; all of which, owing to the absence of lead, are unaltered by atmospheric influences, sulphide of hydrogen, or other emanations.

Sometimes a very permanent and useful paint is prepared from the natural ores of zinc without subjecting them to any of the manufacturing processes already referred to for preparing the oxide of this metal. This is the case with the zinc-stone of Virginia in the United States, which has an average composition of—

Oxide of zinc,	25-00
Carbonate of magnesia,	11-21
Alumina,	17-00
Silica,	28-00

This mineral constitutes a solid rock on the surface of the ground, and when pulverized and mixed with oil in proper proportions, forms on the surface to which it is applied a hard closely-adhering stone coating, impervious to water or fire. Its ordinary tint varies from a

light drab to dark brown. This paint is capable of receiving a high polish.

Oxide of zinc, or zinc-white, besides its application in painting, is valuable for paper-staining, card-enamelling, the bleaching of lace, the glazing of pottery and porcelain ware; and the lighter white portions are used for producing the down on artificial feathers.

Analysis and Testing of Minerals and Compounds of Zinc.—A short summary of the method followed in the assaying of zinc ores has already been laid before the reader. It is almost needless to state that in consequence of the numerous sources of error almost inseparably connected with it, the process so described leads to no very accurate results. Hence in all cases where great precision is required, the liquid process must be adopted. Considerable difficulties are encountered in the analysis of zinc ores, and the compounds of this metal with others with which it is alloyed, in many valuable mixtures used in the arts—arising from the fact that sulphide of hydrogen does not separate members of the fifth and sixth group of bases, namely, mercury, silver, copper, cadmium, arsenic, *et cetera*, from zinc in acid solutions, as was for some time supposed; nor does potassa or ammonia, on the other hand, serve to isolate it from iron, nickel, and other members of the fourth group. These considerations have led to several processes for removing the cause of error, and conducting to more accurate determinations. As regards the action of sulphide of hydrogen, most of the analytical manuals to which the chemical student has access give details which are highly erroneous, and which, at best, serve only for qualitative rather than accurate quantitative determinations; for, in direct contradiction to what is commonly taught, sulphide of hydrogen does precipitate considerable portions of zinc in the form of sulphide from highly acid solutions. This fact was a few years ago very conclusively decided by Mr. C. CALVERT, whose research shows that the above agent cannot be employed in the manner detailed in the manuals to separate copper and other metals of its class from zinc. Again, potassa, which was for a long time supposed to be capable of parting zinc from iron, nickel, cobalt, and manganese, by dissolving the zinc in its excess, leaving the others permanently precipitated as sesqui- and protoxides, is now known to do so only partially; so that under almost every circumstance in which the precipitation is effected, more or less oxide of zinc is found in the separated oxides. Without going, therefore, into long details of the several processes recommended, the most trustworthy, and, at the same time, most expeditious method for the analysis of zinc ores and alloys will here be given.

The ore or alloy should be dissolved in nitric acid, and evaporated to dryness at a moderate heat, exercising the usual amount of care in the operation. If the subject be an alloy into which tin or antimony may have entered, these metals will be converted into insoluble binoxide in the case of tin, and into antimonious acid in case of antimony, particularly if the assay be treated with some fuming nitric acid, as it becomes nearly evaporated. After thorough desiccation the mass is treated with boiling water, filtered

and washed; the binoxide of tin or antimonious acid dried, burned, and weighed with due precaution, and the filtrate with the washings containing copper, cadmium, or other substances with the zinc, as the case may be, treated further. According to FLAJOLOT, the best process is to slightly acidify with hydrochloric acid, and boil the solution, and add hyposulphite of soda in excess to it whilst hot; sulphides of copper, cadmium, *et cetera*, are precipitated entirely free from zinc, by the decomposition of the hyposulphite. After thorough washing, the precipitated sulphides may be dissolved in acid, and the quantity of copper is determined by the processes already detailed under *Copper*; or if cadmium be present the solution may be treated with carbonate of ammonia in excess, and the vessel left exposed for some time, when carbonate of cadmium falls to the bottom, and the copper remains in the solution, to which it gives a deep violet or blue color. After the carbonate of cadmium is filtered off, washed with a solution of carbonate of ammonia and dried, it may be burned and weighed as oxide. The copper may be estimated with a standard solution of cyanide, or of monosulphide of potassium in the usual volumetric way. The zinc, iron, and nickel, with other matters capable of being separated by the reagent, may be thrown down from the solution with protosulphide of ammonium, the precipitate collected, washed, and dried at 212° till it ceases to lose weight; its entire weight is then noted, and the chief part introduced into a German glass tube on a platinum mattress or boat, where it may be heated to redness, whilst a current of sulphide of hydrogen is passed through the apparatus. When the heat has been sustained for a quarter of an hour, the lamp is removed, but the current of gas is still maintained till the tube and its contents are cooled. The platinum boat is then removed, and its contents emptied into a beaker, and treated with dilute hydrochloric acid, containing one part of strong acid in ten or twelve parts of water; sulphide of zinc is dissolved while the sulphides of cobalt, nickel, and iron remain intact. The quantity of the latter may be determined according to the processes which have been given respectively under *Cobalt*, *Iron*, and *Nickel*, and the zinc in the solution may be estimated by bringing the liquid to a boiling heat, and adding sparingly a solution of carbonate of soda, as long as a precipitate is formed, boiling the menstruum for some time to expel all carbonic acid, and then collecting the basic carbonate of zinc on a filter, washing with hot water, drying, igniting, and weighing the residue. During the ignition all the carbonic acid is expelled from the basic carbonate, so that only oxide of zinc remains, from the weight of which that of the metal may be calculated, since 40.0 parts of it contain 32.0 of zinc.

The oxide of zinc contained in ores of this metal may be determined by heating a weighed portion of them, finely ground, to redness for some time, and then treating the powder with a solution of carbonate of ammonia as long as anything is dissolved; the filtered liquid is next evaporated to dryness, and the residue heated to redness and weighed; this weight indicates the amount of oxide of zinc existing as oxide or carbonate in the ore. SCHWARZ, instead of evaporating

the ammoniacal solution of zinc, as in the foregoing, precipitates the metal as sulphide, either by passing sulphide of hydrogen through the liquid, or adding sulphide of ammonium to it. The sulphide of zinc is collected and washed with water, mixed with a little ammonia, and then introduced with the filter into a wide-mouthed flask, where it is treated with an acid solution of sesquichloride of iron, and slightly heated. Decomposition of the sulphide of zinc takes place in this case, and a reduction of a proportionate quantity of the iron salt to the state of protosalt, as explained by the formula—

that is, for every equivalent of sulphide of zinc one of the sesquichloride of iron is reduced to the state of protochloride, while sulphur is separated from the former, and chlorine from the iron salt assimilated. The liquid, as soon as it becomes clear by the deposition of the sulphur, is filtered off, and the quantity of iron in the state of protoxide estimated volumetrically by means of standard solutions of permanganate or of bichromate of potassa, and the amount of zinc deduced therefrom, since 56 parts of iron will represent 32.0 of zinc.

In the analysis of brasses, PELOUZE'S volumetrical method may likewise be resorted to; and, according to CALVERT, with perfect accuracy. The brass is treated with an acid till perfect solution takes place, ammonia is added in excess, and a standard solution of monosulphide of potassium introduced from a burette, whilst a black precipitate forms in the liquid, and until a white one begins to appear. The quantity of copper being found from the volume of liquid used in the precipitation, that of the zinc may be taken as the difference.

Zinc is separated from nickel in many ways. If the alloy containing the two metals be dissolved in sulphuric acid, and the sulphates so produced be treated with acetate of baryta, a sulphate of baryta, with the corresponding acetates of nickel and zinc, will

be produced, with a little free acetic acid in proportion to the quantity of uncombined sulphuric acid which existed in the solution. Sulphide of hydrogen passed through this mixture, throws down the zinc as sulphide, leaving the nickel in solution. The precipitated sulphide of zinc and sulphate of baryta are filtered and washed, then treated with dilute nitric acid to dissolve the sulphide of zinc, and after removing this by filtration and washing from the insoluble baryta compound, the oxide is thrown down as a basic carbonate by treatment with a solution of carbonate of soda at a boiling temperature, then filtered, washed, and estimated as oxide, in the manner already detailed. The nickel can be thrown down as oxide, after expelling the sulphide of hydrogen with caustic soda or potassa, and its weight estimated in the usual way. WÖHLER separates the two metals by adding an excess of potassa to the solution containing them, then a sufficient quantity of hydrocyanic acid to dissolve the precipitate so formed. Double cyanides of the metals with potassium are thus produced, and which behave differently with protosulphide of potassium, the zinc salt only being decomposed by this reagent. By treating the solution, therefore, with protosulphide of potassium, sulphide of zinc separates completely, and may be removed and estimated in the usual way. The filtrate and washings should be evaporated to dryness with strong nitric acid to destroy the cyanogen compound, and the nickel determined by precipitating it with potassa or soda as already indicated.

STATISTICS.—Zinc was not an article of commerce previous to 1822, when it was imported in moderately large quantities, but only to be exported for the most part to India. The applications of the metal in the industry of the nation became gradually extended, till at present the home consumption averages about twenty thousand tons annually. The following table exhibits the imports and exports of the metal from 1823 to 1851; since that period the home consumption has been greatly on the increase, whilst the export remains about the same:—

Years.	Imports.	Exports to India.	Total Exports.	Home used.	Stock in January.	Highest and lowest prices.
1823	5400	4536	4700	—	970	£22 to £23.
1824	9199	7185	8068	24	1140	£24 to £23.
1825	5556	4835	6112	171	413	£22 10s. to £41 10s.
1826	4839	7374	8330	22	924	£28 to £15 10s.
1827	5999	5535	6929	290	1262	£16 10s. to £14.
1828	4566	4806	4943	536	2447	£14 10s. to £11 10s.
1829	4230	3505	3964	684	2012	£12 to £9 7s. 6d.
1830	4422	3385	3479	843	1750	£9 10s. to £11.
1831	3821	2896	3134	941	1512	£11 5s. to £9 5s.
1832	3140	2044	2995	1093	1490	£10 10s. to £11.
1833	2800	1225	1883	1355	1020	£10 10s. to £12.
1834	2100	882	1419	1756	710	£12 to £14 10s.
1835	6500	2497	3943	2205	1350	£15 to £17.
1836	8600	1490	6269	2184	3110	£16 10s., £23 10s., and £19 10s.
1837	4380	1811	3200	2335	2750	£18 10s., £12, and £15.
1838	6265	528	1858	3596	2553	£15 10s. to £20.
1839	8910	1538	3391	4560	3650	£18 5s. to £21 15s.
1840	4965	2637	4091	4181	1536	£20 to £23 10s.
1841	6509	990	1406	3665	2111	£23 10s. to £40.
1842	5500	1584	1900	2641	2800	£36 to £24.
1843	10,173	3459	6445	4125	3750	£23 to £22.
1844	10,393	5826	5925	5388	4021	£22 5s. to £22 10s.
1845	12,903	2969	3084	7459	3296	£22 5s. to £22 15s.
1846	11,434	4875	4967	8450	6800	£22 to £19 10s.
1847	12,729	3301	3631	11,794	2250	£22 to £19 10s.
1848	13,525	2831	3773	9344	2000	£19 15s., £13, and £15.
1849	15,915	3927	5397	8726	2020	£15 to £16 5s.
1850	18,626	3121	4537	11,262	4000	£16 10s., £17 10s., £15, £16 10s.
1851	—	—	—	—	6827	£16 5s. to £15, May 1.

The duty on imported zinc from 1823 to 1825 was twenty-eight pounds ten shillings per ton; this was reduced in 1826 to fourteen pounds; in 1827 to twelve; in 1828 to 1832 to ten, and in 1833 to 1842 to two pounds per ton. The duty levied in 1843 and 1844 was one shilling per ton, and since then all tax upon the imported metal was abolished. The average annual production from 1842 to 1848 was thirty-two thousand five hundred tons, of which—

Silesia made sixty-five per cent.,	or	21,000 tons.
Belgium made twenty	" or	6,500 tons.
Poland made eight	" or	4,000 tons.
Cracow made four	" or	
England made three	" or	1,000 tons.
Total,.....		32,500 tons.

The smelting of zinc declined in England from 1850 till within the last few years that it has been a little more spirited in the several localities mentioned in the commencement of this article; during the same period the Continental establishments, more especially those of Belgium, have greatly enlarged their production. The quantity of zinc produced in the latter country in 1858 was twenty-five thousand six hundred and seventy tons.

The following represents the quantity of zinc smelted in the Prussian States from 1837 to 1848, inclusive:—

1837, ..21,546,600 lbs.	1843, ..36,047,200 lbs.
1838, ..20,983,200 lbs.	1844, ..41,314,100 lbs.
1839, ..21,636,600 lbs.	1845, ..43,861,200 lbs.
1840, ..20,879,800 lbs.	1846, ..43,961,000 lbs.
1841, ..19,977,900 lbs.	1847, ..44,221,800 lbs.
1842, ..27,612,600 lbs.	1848, ..39,873,600 lbs.

Of this quantity there were produced in the upper district:—

	1846.	1848.
In Silesia,.....	35,538,200 lbs.	36,193,100 lbs.
In Westphalia,	189,900 lbs.	75,000 lbs.
In Rhenish Prussia,..	5,322,900 lbs.	3,605,500 lbs.

In France the quantity entered annually for home consumption to about 1848, amounted to eighteen or twenty thousand tons. Estimating the present consumption of that country at thirty thousand tons, that of England at twenty thousand tons, the other Continental nations and America at twenty-five thousand tons, the gross production would appear to average at present from seventy to seventy-five thousand tons annually, a quantity which approximates to the present yield of the several smelting works in operation.

SUPPLEMENTARY MATTER,

BY

PROFESSOR HORSFORD OF AMERICA.

ACETIC ACID.—Insert at foot of column 1, page 3, Vol. I.—The oxidation of the glycerin in fats also appears to be a source of acetic acid. By melting rancid Chinese vegetal tallow—palmitate and oleate of glycerin—in a flask, a strong smell of acetic acid is observed. REDTENBACHER found that an aqueous solution of glycerin is decomposed by the presence of ferments, and yields acetic and metacetic acids. By doubling the formula $C_6 H_8 O_6$ of glycerin, and subtracting 4 H, one obtains $C_{12} H_{12} O_{12}$, that is, three equivalents of the hydrated acetic acid. The oxidation of H_4 by the oxygen of the air, would produce the same result. From this it follows, that the acid reaction of rancid fats and oils, is for the greater part produced by the presence of acetic acid formed by the slow combustion of glycerin.—H.

Insert at foot of column 1, page 16.—A very neat apparatus for making small quantities of vinegar from alcohol, constructed by Dr. SPITALER, has been used in Germany for several years. It consists of a cylinder of glass, ten inches high and eight inches wide, filled up with coarsely-powdered charcoal. A glass cover, with a moderate aperture for the admission of air, closes the top of the cylinder, while a small cock is adapted near the bottom for the removal of the fluid. The apparatus must be kept at a temperature between 63° — 77° . Every evening six ounces of a mixture of one quart of alcohol, specific gravity 0.859, and eleven quarts water, are poured slowly and in a fine stream evenly over the charcoal, after which the cover is laid on. The following morning the corresponding quantity of vinegar may be drawn from the cock.—H.

Insert at foot of column 2, page 16.—It may here be interesting to mention an indirect mode of producing vinegar from wood. During the last few years, especially during the crisis caused by the ravages of the potato disease, serious experiments on a large scale have been instituted, with a view to substitute saw-dust and woody fibre in general for potatoes in the distillation of spirit. Many years ago, BRACONNOT found that saw-dust, cotton and flax fibres, *et cetera*, are converted into sugar by concentrated sulphuric acid. The sugar thus obtained is fermented in the usual manner, and the alcohol generated may be easily converted into acetic acid by any of the processes mentioned in the text. The cheapness of sulphuric acid, and the universal command of woody fibre, open a promising future to the new and ingenious process.—H.

Insert after PYROXYLIC SPIRIT or WOOD NAPHTHA,

page 25, column 2.—It may be well to remind the American readers, that the high duty on alcohol in England, renders the extraction of the pyroxylic spirit from wood a matter of great importance to the chemist. It is usual in England to burn wood spirit in lamps, and to use it generally as a substitute for alcohol, whenever its empyreumatic flavor is not objectionable, as tolerably pure wood spirit can be obtained cheaper than alcohol.

At page 27, middle of column 2, the reader is directed to use either *sulphuric* or *hydrochloric* acid for the purification of wood vinegar. It is far preferable to use hydrochloric acid for decomposing the lime-salt. Sulphuric acid forms with the lime gypsum, which converts the fluid to be distilled into a paste which it is very unpleasant to distil, as it boils irregularly and sometimes with explosions.—H.

The chloride of barium vinegar-test, mentioned at page 34, column 2, may perhaps be objected to, as calculated to mislead those unacquainted with chemical manipulations. In view of this, BÖTTGER has recommended a concentrated solution of chloride of calcium, for detecting the adulteration of acetic acid by sulphuric acid. He found that all kinds of vinegars, whether prepared from wine, alcohol, fruit, or beer, notwithstanding the small amount of sulphates which they contain, are perfectly indifferent to a concentrated solution of chloride of calcium. By adding to two drachms of vinegar a piece of crystallized chloride of calcium of the size of a small nut, and heating the whole to the boiling point, a precipitate of gypsum will fall down on cooling, if the *liquor contains only one-thousandth part of sulphuric acid*.—H.

In connection with the mordant made by decomposing alum by acetate of lead—see page 37, column 1—it may be stated that the preparation of acetate of alumina by double decomposition of sugar of lead and sulphate of alumina, gives rise to immense quantities of sulphate of lead, which is in many localities treated as a worthless refuse. By digesting it with a strong solution of carbonate of soda, it is converted into an inferior kind of white lead, which might be profitably disposed of, or else dissolved in acids for the preparation of lead salts.—H.

At page 41, foot of column 2, it is stated that the vinegar sold contains a small quantity of acetic ether, with the view, no doubt, of improving its taste and odor. It may be added, however, that an interesting formation of this compound was observed in a sour

and decomposed sugar-cane which had been sent from Andalusia to Paris. On splitting the cane open, a very strong smell of acetic acid and acetate of oxide of ethyle was perceptible. It is obvious that the presence of this compound, under the given circumstances, must be explained by the contemporaneous formation of acetic acid and alcohol from the sugar, both of which combine in the nascent state to form acetic ether.—H.

At page 42, column 1, it is stated that for commercial purposes, the protoacetate of iron is manufactured by introducing the materials into a large cast-iron boiler. By employing a copper kettle or boiler, the solution of the iron is effected more rapidly by galvanic action. As long as there is any iron left undissolved in the kettle, the copper will not be acted upon by the acid. A few drops of a solution of bichloride of platinum, added to six or eight ounces of concentrated hydrochloric acid used for dissolving tin, will induce a very violent action, and the tin will dissolve, requiring but little aid by heat. The same takes place when bichloride of platinum is added to the acetic acid for preparing protoacetate of iron.—H.

Insert, in connection with white acetate of lead, page 44, column 1.—It is a well-known fact among phytochemists, that sulphide of lead has a great affinity for coloring matters. Based on this observation, a German chemist proposed to decolor a colored solution of acetate of lead, by the addition of a small quantity of sulphide of potassium or sulphide of calcium. After boiling and filtering, the menstruum is clear and without hue.

ALCOHOL.—At page 50, top of column 1, it is stated that alcohol is never produced except by the vinous or alcoholic fermentation of particular substances. There is one exception to this rule. Pure olefiant gas is absorbed by agitation with concentrated sulphuric acid, with formation of sulphovinic acid; and by diluting the latter compound with water, and distilling the fluid, alcohol is obtained. This fact was discovered twenty-seven years ago by HENRY FLENNEL, though, singular to say, the discovery has lately been claimed by BERTHELOT.—H.

Insert at foot of column 1, page 107.—*Dunder* fulfils two important offices in the distillation of rum. In the first place, the large quantity of acetic acid contained in it, and formed at the expense of alcohol during fermentation of the wash, serves to decompose the sugarate of lime, contained in the generality of West India molasses in considerable quantities. It is for this reason that *dunder* increases the yield of rum. Sugarate of lime does not ferment, and when present in considerable quantity, actually opposes the fermentation of the wash; so that without *dunder*, fermentation would proceed so sluggishly that most of the alcohol would be converted into vinegar. This occurrence might be avoided by adding the diluted molasses containing sugarate of lime, to its own bulk of strongly fermenting wash. The carbonic acid of the fermenting liquor would then perform the office of the acetic acid of the *dunder*, by precipitating the lime as carbonate of lime and liberating the sugar. The American Editor disproved the idea that *dunder* is connected with the fine flavor of rum, by two experiments. In

one trial, molasses—from which all the lime was precipitated by sulphurous acid—and water only were used. The resulting rum was a very fine-flavored spirit, and the yield was perceptibly greater than from molasses not thus treated, though from similar cane. Another trial was made by partially filling the rectifying vessels or retorts, as they are called in Jamaica—they are like the wash-heater, as prepared B, Fig 78, and connected with the still in the same manner—with *dunder*, with a view to increase the flavor of the rum, as might be expected if the flavor proceeded from that source. The rum, however, thus obtained had the disagreeable flavor of the *dunder* totally different from that of *Old Jamaica*. The flavor of the rum appears to depend entirely on the presence of a fusel-oil, the formation of which is immediately dependent on the proportion of the surface of the wash exposed to the air during fermentation, to its entire volume. It is well known that two contiguous sugar plantations will produce very different qualities of rum, though operating in the same identical way. But it has been observed that in such cases the size and the exposed surface of their fermenting vats were different, or if not, the stills were of different capacity. The protracted boiling of the wash in very large and deep stills, injures the flavor by increasing the empyreumatic products. From the above observation it would follow, that the origin of the genuine flavor is intimately connected with the more or less complete oxidation of the molasses ferment induced by the greater or smaller surface of the wash—compared with the bulk—exposed to the air. Large cubical cisterns, holding one thousand and more gallons, yield an inferior rum, as compared with smaller vats having a larger exposed surface. Similar observations made by LIEBIG with regard to Rhenish wine appear to confirm this opinion.

The second office fulfilled by *dunder*—an office of some importance for the more rapid development of fermentation—is by its richness in ferment. The colonial distiller does not employ any yeast for inducing fermentation of his wash; he is consequently obliged to work upon more dilute solutions of molasses and skimmings—collectively called *sweets*—than are used by his continental competitors. Any, even the slightest source of ferment, must therefore be welcome for his purpose. *Dunder* is such a source. Ferments, it is well known, are destroyed by boiling-heat of water, and recent *dunder* is in that respect perfectly inert; but by exposure to air in shallow tanks, an oxidation and regeneration of the *killed* ferment takes place, and it is to this circumstance that a part of the favorable action of *dunder* must be ascribed.

Without the assistance of *dunder* a more rapid fermentation of the wash may be obtained by converting the cane-sugar contained in molasses into grape-sugar, by treatment with a small quantity of acid, which is subsequently neutralized. It has been stated that less ferment is required for converting grape-sugar into alcohol than cane-sugar, a fact which will render it less miraculous to hear that some plantations manufacture a superior rum while their sugar is nearly as dark as coal-tar. Molasses from such sugar contain chiefly grape-sugar. Allusion has already been made to the

fine flavor of rum made from molasses which were obtained by boiling sugar with an excess of bisulphite of lime.

Cleanliness in the operation of the distilling is a standard admonition of the theoretical world, woefully disregarded by the practical. In fact, it appears that a premium is offered to malpractice in this instance, as many of the most detestable colonial distilleries turn out very creditable produce. Whether the exception proves the rule in this case, must be left undecided. However, if cleanliness is not absolutely required for improving the flavor of the spirit, it would be a charity to the still-house bookkeeper, who is condemned to pass part of his lifetime in these disgusting dungeons.—H.

Page 117, column 2, *Alcoholometry*.—To the analytical chemist it happens sometimes that only small quantities of the alcoholic fluids are at his command. In such cases it is almost impossible to obtain a correct result, by determining the specific gravity of the few drops of alcohol obtained by distillation. It is safer to subject the alcohol obtained to an organic analysis by combustion with oxide of copper, and calculate the quantity of absolute alcohol from the resulting carbonic acid and water. This is of course only applicable when the alcohol does not contain other volatile bodies, like ethereal oils, *et cetera*.

ARSENIC.—At the top of column 2, page 215, Vol. I., insert—In the presence of oxide of iron, minute quantities of arsenic cannot be detected by the blow-pipe. In that case, the oxide of iron must be treated with a boiling solution of potash, which is afterwards neutralized by sulphuric acid, and tested in MARSH'S apparatus.

In same page and column the reader is directed to drop a few fragments of pure zinc into MARSH'S tube-apparatus. It deserves to be remarked, however, that pure zinc, especially when in large pieces, frequently dissolves so slowly in dilute sulphuric acid, that it is impossible to obtain a steady hydrogen flame. The addition of a drop of bichloride of platinum, or of a small quantity of platinum black, will remedy this difficulty. If the fluid to be tested contains any considerable quantity of arsenic acid, this alone is sufficient to produce a violent reaction of the acid on the zinc.—H.

BALSAM.—Vol. I., column 1, page 223.—*Canada Balsam*.—This balsam is mostly used by optical instrument-makers for cementing together the different parts of achromatic lenses, NICHOL'S prisms, *et cetera*. It may be here added that Japan varnish is a balsam derived from *Rhus vernix*, and serves to impart a brilliant lustre to metallic and other objects, hence denominated *japanned articles*.

BEER.—In connection with the analysis of beer, pages 281–284, the following may be given:—

ANALYSIS OF VARIOUS KINDS OF CELEBRATED BEER.

	Water in 100.	Extractive matter.	Alcohol.	Carbonic acid.	Analyst.
Barclay's ale,	86.93	.. 6.02	.. 6.90	.. 0.15	Raiser.

BENZOL.—Insert at foot of column 1, page 286, Vol. I.—The rectified volatile oil from coal-tar, distilling between 212°–320°, and consisting mostly of benzol, toluol, and cumol, has been strongly recommended for oil paint in the place of oil of turpentine. It has the advantage of evaporating rapidly, whereby apartments painted with oil paint are rendered much sooner inhabitable.

A curious and interesting application has been made of benzol by the well-known photographer, M. DE ST. VICTOR, based upon the property of this fluid, to be lighter than water and insoluble in it, and to be kindled with the greatest facility by a small flame in contact with air even at low temperatures. He found that benzol, to which have been added a few pieces of potassium or phosphide of calcium, readily inflames when thrown on water. An experiment was made on the Seine in Paris, in which three hundred grammes of benzol were inclosed in a glass-bottle, with half a gramme of potassium. The bottle was floated down the river, and suddenly broken. The potassium ignited and set fire to the benzol which burned with an immense flame, which, though smoky, had great intensity, and lasted fully a minute in spite of a strong breeze.

A repetition of this experiment in the fountain of the garden of the Palais Royal gave the same result. In spite of a heavy rain, the flame lasted over a minute.

M. DE ST. VICTOR proposes a mixture of benzol with sulphide of carbon in which phosphorus has been dissolved, as a close imitation of the famous liquid Greek fire.—H.

BISMUTH.—Insert at foot of column 1, page 288.—An alloy for galvanoplastic moulds is prepared by fusing together eight parts of bismuth, eight parts lead, three parts tin. This mixture melts at 225°. For preparing the mould, the alloy is fused and poured into a paste-board boat of about one quarter inch depth; it is then stirred with a heated iron-wire until its surface is perfectly even and bright. As soon as it has acquired a pasty consistence, the medal to be moulded is slightly heated, and immediately pressed on the alloy, and kept under pressure until cool.—Böttger.

BLEACHING.—Insert at foot of column 1, page 315, Vol. I.—Mr. L. BENNER, chemist of KÖCHLIN'S print-works at Darnetal, near Rouen, has lately recommended the use of sugarate of lime—sugar-lime—in place of caustic lime for bleaching of cotton fabrics. He describes his process as follows:—For one scouring operation, two hundred pieces of fourteen pounds each are worked upon, and the operation is performed in large kiers, heated on the open fire, and under a pressure of about twenty-two pounds to the inch. As soon as the pieces are singed, they are passed through a washing-machine—similar in principle to ROBINSON'S—in order to moisten them sufficiently to prevent any danger of combustion. After this they are wound by a mechanism into a tub in which they are spread in large folds. During the latter operation a milk of lime, containing forty pounds burnt lime, runs on the pieces in such proportion that the forty pounds of lime will be used up by the two hundred pieces. From this liming tub the pieces are mechanically transferred to the bucking kier, in which

they are arranged in separate layers. After covering and fixing the fabrics by wooden cross-bars, as much water is added as will cover the pieces to the height of twelve inches, after which the sugar-lime is added. The latter is prepared by mixing in a tub thirty pounds burnt lime with seventy-two pounds boiling water; after slaking, thirty-six pounds more of hot water are added to dilute the lime-paste. To this milk of lime are added fifteen pounds of molasses, previously diluted with thirty-six pounds of hot water. The whole is well stirred and thrown into the bucking kier, whereupon the cover is fastened, and the charge kept boiling for eight hours. The fire must, however, be increased very gradually, so that the operation is finished in about ten hours.

This operation ended, the pieces are taken out, passed twice through the washing-machine, and brought back again into the bucking kier. The pieces are folded up as before, covered with twelve inches of water, which is mixed with the sugar-lime prepared from thirty pounds of burnt lime and ten pounds of molasses. The charge is again boiled during eight hours; the pieces are then removed, passed twice through the washing-machine, and steeped in hydrochloric acid of specific gravity $1.010 = 2^\circ$ Twaddell during four hours. They then undergo two washings—are brought back to the bucking kier a third time to be finished for bleaching by a single soda-ley.

The sugar-lime being readily soluble in water, and acting in all respects like free lime, has, of course, the great advantage of intimate contact with all the particles of grease and resinous substances which are fixed on the fibre; while the caustic lime, in consequence of its restricted solubility, especially in boiling water, is less complete in its saponifying functions.

The bleaching process is carried out as follows:—After packing the pieces in the bucking kier, and covering them with twelve inches of water, a solution of sixty pounds of soda-crystals is added, the cover of the kier fastened, and the charge boiled for three hours. The fire is then withdrawn, the steam allowed to escape, and the cover removed. The soda liquor is drawn off and replaced by cold water, to which a resin-soap, prepared of one hundred pounds of soda ash and one hundred pounds of resin, is added. The cover is replaced, and the charge boiled for twelve hours, after which the soap-ley is withdrawn, the kier filled up with cold water as before, a solution of sixty pounds of soda crystals added, and the charge again boiled for three hours. The pieces are now removed to undergo the washing process twice, before being wound into the bleaching solution of chloroxide of calcium, where they remain a few hours; hence they pass through water, then receive a scouring in weak hydrochloric acid, and pass twice through the washing-machine.

Pieces which have not been treated with solution of chloroxide of calcium, are equally as well adapted for dyeing purposes; and the treatment with bleaching liquor may therefore be dispensed with for the greater part of the pieces.

The first scouring with soda crystals is intended to remove traces of acid, and most of the resinous matter, to prepare and aid the action of the resin-soap.

The second boiling with soda crystals is to remove

the remainder of resinous substances, and also to free the fibre from adhering rosin-soap.

This method of giving two scourings with sugar-lime offers the great advantage over those methods, where only one scouring with a comparatively strong ley of lime is employed, of weakening the fibre in a less degree.

ANTICHLORINE.—The property of cotton and other woody fibre to condense gases and colors on its surface by a peculiar physical attraction, is well understood. This action, which it has in common with all solid bodies, is so powerful in some instances, that it may even counteract chemical attraction. Cotton and other vegetal fibre which has undergone the bleaching process by chlorine, for instance, has the property of powerfully retaining some chlorine gas. The difficulty of removing this effectually from the bleached fibre is almost insurmountable, requiring a great sacrifice of time, when rapidity is so essential, besides large volumes of water and increased machinery. Now, in order to insure the proper rapidity of the manipulations, either an appreciable amount of chlorine must be left in the bleached fabric or paper-pulp, or else this chlorine must be removed by substances bringing superior chemical affinity into play.

The expedient of only partially removing the chlorine from cotton cloth is certainly in favor of the manufacturer, to the evident disadvantage of the consumer. Chlorine acts gradually on the fibre; it combines with its hydrogen and disorganizes it, renders it brittle, aided by the hydrochloric acid formed. The same is the case with paper-pulp. The action of chlorine left in the bleached pulp is particularly illustrated by the paper manufactured in France soon after the introduction of chloroxide of calcium into the paper-mills. The paper, on running over the hot drying rollers of the machine, becomes brittle; the books printed on it gradually become full of brown spots, and acquire a uniform brownish tint. Every bookseller is acquainted with the inferiority of the modern printing paper in this respect. This deterioration must be entirely ascribed to the action of free chlorine, adhering to the fibre. It is not the paper alone that suffers; the type, too, with which it comes in contact, is affected in proportion to the amount of chlorine left in the paper. It is well to direct the attention of paper-makers and printers to this point, and so furnish them with a ready explanation of the rapid deterioration of the paper and type, and to draw their attention to those chemical agents which may be employed with advantage for counteracting these evils. Agents of this description have been introduced to the public under the general designation of *antichlorine*.

Carbonate of soda or ammonia was first proposed as an antidote for chlorine; but though the latter gas decomposes soda or ammonia in concentrated solutions, the effect in very dilute fluids is very insignificant, and requires the aid of heat. Sulphide of calcium was next introduced; but its property of being decomposed by carbonic acid, with evolution of the fetid sulphide of hydrogen gas, and the black precipitate which it produces with any salt of iron or copper which may be present in the pulp by accident, preclude the use of

this salt. Protochloride of tin—tin salt—and a mixture of protosulphate of iron and salt, have the disadvantage of introducing metallic salts into the pulp, which are about as objectionable as chlorine itself. Hyposulphite of soda is somewhat expensive, and precipitates sulphur when brought in contact with chlorine or hydrochloric acid, the sulphur giving a yellowish tint to the paper. Recently a patent was taken out by ROTH and LEA of Philadelphia, for the use of a solution of sulphite of soda as an antichlorine. Sulphurous acid and its salts are indisputably the most economical, besides being the most efficient chemical compounds for removing free chlorine. Sulphurous acid alone, however, cannot be employed for the purpose in question, on account of being converted by chlorine into sulphuric acid, which has a detrimental action on woody fibre. The sulphite of soda answers, therefore, all practical purposes, as far as its chemical action is concerned; it is, however, still liable to the objection of difficult transportation in its fluid state, in which it must be sold for reasons of economy, entailing additional expense on the consumer for water-tight casks and freight of a valueless substance—water. These considerations, which oppose a more general application of the sulphite of soda, have induced Professor HORSFORD to make the use of the cheap sulphite of lime or *antichloride of lime*, the subject of a patent for England and America.

It may appear on first consideration that neutral sulphite of lime, which is very little soluble in water, could have but little effect on the chlorine combined with the fibre; but the fact that hydrochloric acid dissolves neutral sulphite of lime with formation of soluble bisulphite of lime, will readily explain its action. Now hydrochloric acid is invariably generated whenever chlorine gas acts as a decoloring agent on organic substances.

It is the hydrochloric acid thus generated which dissolves the neutral sulphite of lime. Contact with chlorine converts the sulphite into sulphate of lime, which goes to increase the weight of the paper, and practically saves to the manufacturer nearly or quite the whole cost of the sulphite of lime. The article is prepared by agitating milk of lime by means of revolving paddles in a long close box, with fumes of burning sulphur, until the reaction is neutral or acid. It is then drained and air-dried, and packed in casks for transportation.

In connection with the formula given at page 324, column 2, it deserves to be stated that, instead of taking the protosulphate of iron— FeOSO_3 —for the preparation of sulphurous acid, it is more advantageous to employ the *sesquisulphate of iron*— $\text{Fe}_2\text{O}_3, 3\text{SO}_3$ —which is obtained by *roasting* green vitriol in the air, and then adding to it half as much more sulphuric acid as it already contains, and evaporating the resulting pasty mass to dryness. One hundred and ninety-eight parts of the dry sesquisulphate of iron are now mixed with eighty parts of sulphur, and heated, whereby one hundred and ninety-two parts of dry sulphurous acid gas are obtained:—

while one hundred and ninety-eight parts of the *protosulphate of iron* will only yield one hundred and sixty-nine parts of sulphurous acid.—H.

BLEACHING POWDER.—At page 328, immediately preceding the formula at foot of column 1, it is stated that the chlorine employed in the experiments was prepared by adding hydrochloric acid to chlorate of potassa. But BÖTTGER found that the gas thus obtained contained Cl O_3 . It is to be presumed that the mixed gases were passed through sufficient water, and at a rate sufficiently slow to permit the entire absorption of the Cl O_3 .—H.

At page 329 a description is given of FRESENIUS and WILL's method for testing the quality of manganese ore. A modification of this method, more simple, and still equally satisfactory for practical purposes, has been proposed by MOHR. It is executed in the following manner:—Three grammes of the finely-powdered and dried manganese ore are mixed in a small glass flask with a little water, and enough sulphuric acid to render the whole mass perfectly fluid. This flask and a porcelain capsule containing about nine grammes of crystallized oxalic acid, are now placed in one scale of the balance, and brought into equilibrium by a basin of sand or small shot. The oxalic acid is now thrown into the flask, where it immediately begins to reduce the binoxide of manganese under evolution of carbonic acid. To accelerate this decomposition, it is good to give the flask a circular horizontal motion, until the evolution of the carbonic acid has ceased, and the mass from black, which it was, has become light-colored. The empty porcelain capsule and the glass flask are now again placed on the balance, and so much weight placed into the capsule as to restore the equilibrium. The weight required to effect this is equal to the weight of a binoxide of manganese in the ore, because one equivalent of binoxide of manganese = 44, when treated with oxalic and sulphuric acids, cause the evolution of two equivalents of carbonic acid = 44; one part by weight of binoxide of manganese is therefore indicated by one part of carbonic acid.

Now, as three grammes of ore have been employed for the above experiment, it follows that the amount of carbonic acid lost, divided by three, indicates the amount of binoxide of manganese in one gramme of the ore; and by multiplying the latter number with one hundred, the per centage of the binoxide is obtained. The error produced by the loss of water in this method does not signify for most practical purposes, but may be remedied by closing the flask with a cork in which a glass tube filled with dry chloride of calcium is fastened. In this case, however, the carbonic acid contained in the flask when the experiment is finished must be removed by suction.—H.

BONE BLACK.—At page 336, eleventh line of first column, it is stated that solutions of sugar are better deprived of their color when alkaline than when acid. This, however, only applies to an alkalinity of sugar sirup produced by *lime*.

Some interesting reflections are suggested by the remark which follows in the same column with reference to the decoloring power of carbon, and M. BUSSEY's

experiment, showing that the reaction is strongly influenced by ordinary chemical forces, instead of being purely mechanical. As the whole universe, with all its diversified phenomena, derives its origin from one *primum movens*, and as all the phenomena connected with matter can therefore only be functions of this creative unit, one may, *a priori*, expect that which is actually observed, namely, the gradual transition and intimate connection of varied effects and causes. Where does inorganic nature cease and life commence? Where stops the action of light, and where does heat begin? Why does magnetism induce electricity? Where do the physical forces—cohesion, repulsion, heat, electropolarity, light and contact force, find a landmark which separates them from what are denominated chemical forces? Every effect must have a cause, and every distinct effect a distinct cause; but it is the defect of the human mind to be slow in distinguishing apparent from real differences. Before NEWTON it would have been undoubtedly considered good logic to conclude, that the force which made the apple *fall* was different from that which kept the earth *steady*. Thus it comes that all definitions of isolated systems fail, and undergo continual amputation and restoration with every progress of science—now hobbling on one bandaged leg, now on another—showing that nature abhors, if not the vacuum, at least systems and definitions; and it teaches that there is no gap in its mechanism, no wheel or spring wanting in its clock-work; in fine, there is no interruption in its development from a single cause or *animus* to its utmost complicity, which is observed in the perfection of organic existence. A disruption in the continuity of effects in the economy of nature would be equal to the interruption of an electric wire between two telegraph stations; because in that case the intelligent cause on one station could no more produce an intelligent effect on the other, in consequence of an apparently insignificant accident. The forces as connected with the phenomena of matter, are in the same predicament. There can be no *real* difference in the so-called forces, because such a difference would constitute a *real* gap; it would stamp the force as an individual, producing an individual effect, so that all the infinitely different effects observed must be ascribed to infinitely different forces.

The attraction of coloring matter by charcoal is denominated mechanical, while the attraction of sulphuric acid by baryta is classed with chemical effects. But animal charcoal does not only attract coloring matter; it also decomposes metallic salts, and fixes their base by that same power of retention. Now it is known that chemical combinations and decompositions are produced by differences in intensity of one only chemical attractive force called affinity. It is evident that the same force is inherent in animal charcoal. This view is corroborated by the fact that animal charcoal absorbs different compounds in different but determined quantities. NIEPCE has shown that iodine and chlorine gas are condensed by the inked portion of printed paper, while the white portion of the paper does not retain any of the gases. Charcoal absorbs heat and light most readily. It condenses

electricity on its surface, and thereby acts as a non-conductor, the same as glass, which is only an isolator in consequence of its great attraction for electricity. Metallic charcoal loses, with its power of attracting colors and gases, also the power of attracting electricity, which latter now passes through without hindrance, as through other conductors. Ordinary charcoal condenses gases, and frequently causes chemical combinations. This substance, then, shows the gradual development of chemical effects by physical forces. The effect of animal charcoal depends entirely upon its porosity and the extent of its carbonaceous surface, and is directly proportional to it; and it may therefore be presumed that if the surface of charcoal could be indefinitely increased by solution in water, it would produce all the powerful chemical phenomena of cyanogen or ozone.

If one moves on a step further, binocide of tin presents itself, a substance already more pronounced in its chemical character than charcoal. Still it is inclined to combine equally as well with bases as with acids, showing a transition character. Now, if pumice be soaked in a solution of bichloride of tin, and then dipped into a solution of carbonate of soda, the pumice acquires all the properties of animal charcoal. Very porous pumice, finely-divided silica, cotton fibre—all these show signs of chemical power depending on their extent of surface; and it may well be supposed that this chemical power would be more prominent, could they be obtained in the fluid state. Silicic acid, which is as inert as charcoal at the ordinary temperature, drives out the powerful sulphuric acid from its combinations at a temperature nearer its own melting point.

Another phenomenon is also connected with the action of animal charcoal, namely, that of endosmosis. It has been shown, as subsequently stated in the text, that a colored sugar solution containing, besides water, some salts, does not pass unchanged through animal charcoal. Pure water is the first to pass through, then comes water with salts, then sugar, and lastly, the color. From this one concludes that animal charcoal has the greatest affinity for coloring matter, less for sugar solution—because the latter is replaced by the former—still less for salt solution, and least of all for water. Could, therefore, a thin diaphragm be constructed of animal charcoal, one would observe the endosmosis to take place from a salt solution into water, and from a solution of sugar into salt, and from a solution of coloring matter into water, salt, and sugar; that is, of such tinctorial matter as has the greater affinity for animal charcoal. Thus a certain molecular attraction in animal charcoal may produce effects ascribed to a multiplicity of forces, as mechanical force—adhesion, endosmotic force, catalytic force; and chemical force—affinity. Would it not be more rational to consider all these as mere functions of the same molecular tendency the intensity of which alone gives rise to variable effects, the same as is observed in sound, electricity, and light?—H.

CORRENWINDER assumes that the decoloring effect of animal charcoal is correlative to its absorbing power for lime; and on this supposition he bases the following method for determining the commercial value of bone

black:—A solution of sugarate of lime is prepared, containing, say, twenty grammes of lime in one thousand cubic centimetres fluid, which are neutralized by one thousand cubic centimetres of a standard solution of sulphuric acid, so that fifty cubic centimetres of the acid solution indicate one gramme lime.

The samples of the bone black are now rendered of a uniform condition, by passing them separately through the same sieve, after having removed the fine dust by a paper fan. Fifty grammes of each sample are placed each in a glass flask. In each glass flask one hundred cubic centimetres of the solution of sugarate of lime are added to the bone black, and the whole allowed to digest for an hour. After this the fluid of each flask is filtered separately, and fifty cubic centimetres of the filtrate liquor are tested for the amount of lime with the standard solution of sulphuric acid. The more lime there is absorbed by the bone black, the less sulphuric acid will be required to neutralize the filtered liquor; and that liquor which requires least acid for neutralization, must have been in contact with the most valuable sample of bone black, so that the value of the animal charcoal increases directly as the amount of standard acid required for neutralization decreases.—H.

BORACIC ACID.—At page 342, it is stated that boracic acid scarcely reddens vegetal blues, and renders turmeric brown, like an alkali. This reaction affords an easy means of detecting boracic acid in its combinations, by adding to it a little hydrochloric acid; after which dip into the fluid a piece of turmeric paper, and then dry it. If a trace of the acid was present, the paper will have a brown stain after drying.—H.

BREAD.—Insert at foot of column 1, page 377, Vol. I.—The frequent failure of the grain crops, and the scarcity of grain induced by some other accidental causes, has drawn the attention of chemists to the process of bread-baking, either with a view to discover some substitute for wheat flour, or else to find the means for rendering the whole of the nutritive principles of the cereals available for consumption. The latter direction has already furnished valuable results. It is known that the bran separated from flour contains a comparatively large proportion of nitrogenized substance, namely, that constituent of the flour which contributes most to nutrition. Until quite recently the bran was lost to the nutrition of man. Now, however, it has been shown that this nitrogenized substance may be extracted from the bran without much trouble and expense, so as to obtain the whole of its valuable matter. This process, recommended by a number of chemists, was ultimately patented in France by a Mrs. DURUT. The manipulation is carried out in the following manner:—Bran is mixed up with boiling water in a kettle over a moderate fire, so that the mixture has a semifluid consistency. The mixture is now heated carefully until the bran loses its raw smell—not till it is cooked; it is then transferred into bags and pressed. The pressed cake is treated once more in the same manner, mixing it with water, allowing to boil for a short time, and pressing. The fluid obtained by this second operation is used, instead of pure water, for a fresh portion of bran. By the first pressing a sirupy

juice is obtained, completely saturated with gluten, and which is destined to replace the pure water in the process of bread-baking; thus gaining for the bread a large proportion of valuable nutriment entirely lost before. The economy of this process is thus stated:—A bag of flour of the average weight of three hundred and twelve pounds, made into bread with water in the usual manner, yields on an average one hundred and four loaves of four pounds each. A bag of flour of the same weight, made into bread with the extract of bran, yields one hundred and thirty loaves of four pounds each, or a clear gain of twenty-six loaves over the old process. Twenty-five per cent. increase in the yield of bread from the same amount of flour is a fact the importance of which cannot easily be exaggerated.

BROMINE.—The process detailed at pages 393, 394, for the separation of bromine and chlorine, may with advantage be modified in the following manner:—Precipitate the solution containing chlorine and bromine with nitrate of silver; wash, dry, and heat the precipitate to a state of semi-fusion in a weighed porcelain capsule. Weigh the capsule with the silver precipitate, then reduce the latter with the aid of zinc and sulphuric acid in excess. Wash out the reduced silver, ignite, and weigh it. If one supposes the weight of the chloride and bromide of silver to be a , and that of the metallic silver obtained from it by reduction with zinc to be b , and the amount of chlorine to be x , the amount of bromine will be $a-b-x=y$. From this we conclude:—

$$\frac{107.97x}{35.46} + \frac{107.97y}{79.97} = C.,$$

from which is deduced:

$$x = 1.38674C - 0.79667a$$

That is, multiply the weight of the reduced silver by 1.38674, and deduct from the result the product obtained by multiplying the weight of the chloride and bromide of silver with 0.79667, and the result will be the amount of chlorine in the mixture. By subtracting the weight of the chlorine plus that of metallic silver from the weight of the chloride and bromide of silver, the amount of bromine is obtained.—H.

CANDLE.—Read, in connection with the processes described at pages 430, 431:—The operations of saponification of the fat, and decomposition of the lime-soap by sulphuric acid, have been hitherto effected in open vessels, under the ordinary pressure of the atmosphere. An improvement on this plan has been recently proposed by M. DELAPCHIER, of Besançon, who substitutes close vessels in order to saponify the fat. Wash and decompose the lime-soap under a pressure of about twenty-two pounds to the square inch, by which the operations are considerably facilitated, and their duration shortened. The products by this process are said to be superior to those obtained in open vessels, and a considerable economy of fluid is effected. The apparatus consists essentially of a horizontal boiler, with a man-hole and two safety valves at the top. The heat is furnished by a large steam-pipe, running in a depression along the bottom of the boiler. The

pipe is perforated with numerous holes to distribute the heat more uniformly. A horizontal iron shaft, which passes through stuffing boxes in the heads of the boiler, carries an agitator, the transversal ribs of which nearly touch the circumference of the boiler. A large pulley at one end of the shaft receives its motion from a suitable motor. The materials are charged through the man-hole, and at the end of the operation withdrawn by a large valve at the bottom of the boiler.—H.

CAOUTCHOUC.—The qualities of sulphurized caoutchouc are described in column 2, page 448, vol. 1 :—Allowing the chemical composition of caoutchouc to be $C_8 H_7$, the formula of the best vulcanized rubber car-springs is found to be very near—

R signifying one equivalent of rubber= $C_8 H_7$. It rubber was represented by $C_{64} H_{56}$ —or eight times its present equivalent—the vulcanized car-springs would have the compact formula :—

CIDER.—At page 475, middle of column 2, it is stated that in warm seasons it is still a desideratum to discover some means of checking a too rapid fermentation of cider. The process for the prevention of fermentation in saccharine solutions, denominated *mutisme* by the French, may be very easily applied for effecting this purpose. By adding to fermenting powder from one six hundredth to one thousandth of neutral sulphite of lime, or of bisulphite of soda, the fermentation may be reduced to a minimum, or entirely checked.
